OBSTETRIC AMNESIA, ANALGESIA AND ANESTHESIA

THEIR RELATIONSHIP TO SUDDEN DEATH
IN LABOR

THADDEUS L. MONTGOMERY, M.D.
PHILADELPHIA

No topic in obstetric procedure is receiving more despread attention than amnesia and analgesia. Those who practice the art of midwifery are well aware of this fact, for the journals are filled with reports of new methods and assorted combinations, and every patient who comes to register wants first to know what will be done to eliminate the pangs of labor. She expects to fall asleep with the first pain and awake with the baby in her arms, and she is sure from her reading that this is not only feasible but her rightful privilege.

By taking it on themselves to adopt each new obstetric method of analgesia or anesthesia and announce it as a panacea for women's suffering, lay periodicals play a major rôle in producing this misconception. Their articles are a medley of false impressions and incomplete truths, but they are widely read and exert sufficient popular appeal to force on the profession methods of management that may prove innately unsafe or poorly adapted to peculiar localities and conditions of practice.

Then too, enthusiastic reports in professional journals lead the physician to employ in his obstetric practice methods of analgesia the difficulties and dangers of which are insufficiently emphasized. At the height of the popularity of a new method, medical reports seem persistently favorable. Only when the method is taken on to the centers of propagation and put to general use do discrepancies and questions arise. This is true of the present widespread use of the barbiturates for the purpose of inducing deep amnesia. While reports of the method have been favorable,¹ individual obstetricians are beginning to question its efficacy, and unfavorable reactions and peculiar deaths are being reported.

So impressed have I been by the number and the nature of anesthetic deaths reported before the Maternal Welfare Committee of the Philadelphia County Medical Society that I have undertaken to

determine what part analgesia plays in maternal mortality in that city and to compare the various methods of analgesia on the basis of their safety and efficacy in general usage. The study is based on a five year period, 1931 to 1935 inclusive.

Inspection of the results over this period of time reveals that the general mortality rate has decreased 24 per cent, that this decline is accounted for by a 49 per cent decrease in nonpreventable death rate, and that the preventable death rate has remained uniform (table 1). In the instance of maternal death during labor or within twenty-four hours thereafter there is no lessening of the general rate; the nonpreventable death rate has decreased by 49.3 per cent, and the preventable rate has risen 52.5 per cent; the death rate attributable to errors in judgment and technic on the part of the physician has risen 108.5 per cent, and the proportion of maternal deaths due to these errors has increased 107.3 per cent (table 2).

From these figures one receives the impression that mistakes in judgment and errors in technic as represented by deaths in the intrapartum period account for the slowness of improvement in obstetric practice. This observation is supported by a study of the trend in all other deaths. In all other maternal deaths there is a general decrease of mortality rate of 28.9 per cent, a decrease in the nonpreventable death rate of 48.6 per cent, a decrease in the preventable death rate of 11.1 per cent, and a decrease in the death rate due to errors in judgment and technic on the part of the physician of 41.4 per cent (table 3).

There is an improvement then in all phases of obstetric practice as represented in the group of 876 deaths, but in the smaller group of 220 intrapartum deaths there is such a lack of advancement that no net progress in preventable death rate for general obstetric practice is demonstrable (table 4).

Apparently something is wrong with methods of management in labor, and saddest to relate, whatever is wrong is going more astray with each succeeding year. Probably a number of matters are at fault, but of this complex problem I believe that obstetric amnesia, analgesia and anesthesia constitute an important portion.

In formulating an opinion as to the acceptability of an anesthetic or analgesic method the physician must have in mind the following points: first, safety; second, the amnesic, analgesic or anesthetic properties; third, effect on contractions of the uterus; fourth, advantages or disadvantages in special cases; fifth, untoward reactions and idiosyncrasy; sixth, constitutional effects; seventh, effect on the fetal respiration at birth.

With these considerations in mind let us take note of the agents that were used in the 220 intrapartum deaths, compare their good and bad features and determine the part they played in death (table 5).

Dr. Philip F. Williams, chairman of the Maternal Health Committee of the Philadelphia County Medical Society, gave his permission to use the committee's records; Dr. T. Ruth Hartley Weaver gave her generous assistance in collecting the data.

ETHER

Ether, with or without nitrous oxide-oxygen induction, was administered by inhalation to 108 of the patients who died. In one instance it was indicated as the real cause of death and in another as a possible cause. In both cases it was poorly administered. Bad judgment was shown in its selection as an anesthetic agent in one additional case.

Ether appears to be still the most widely used and possibly the safest of anesthetic agents in obstetric

Comparison of Rates in 1931 and 1935

Maternal death rate.....	{ 1931—79 1935—60 }	Decrease of 24%
Nonpreventable death rate.....	{ 1931—37 1935—19 }	Decrease of 48.9%
Preventable death rate.....	{ 1931—42 1935—41 }	No change (1%)
Death rate from errors in judgment and technic on part of physician.....	{ 1931—21 1935—19 }	Decrease of 9.5%
Proportion of maternal deaths due to errors in judgment and technic on part of physician.....	{ 1931—26% 1935—28.9% }	Increase of 11.1%

practice. It may be employed for analgesic effect in early labor in the Gwathmey technic, as "whiffs" during the second stage, or pushed to complete anesthesia by deep inhalation. It does inhibit the activity of the uterine musculature; its free administration may stop labor pains and its long continuance predispose to relaxation and postpartum hemorrhage.

It has the advantage of simplicity of technic, ease of administration and wide margin of anesthetic safety. It is of essential value for types of delivery that require relaxation of the uterus; namely, decomposition of the breech and internal podalic version and extraction. It can produce greater relaxation than is necessary for low forceps.

Its administration is singularly free of untoward reaction and idiosyncrasy, although patients vary decidedly as to degree of postanesthetic nausea, vomiting and prostration. Its use for inhalation is to be avoided in instances of pulmonary disease. Administered by the open drop method, ether does not interfere with oxygenation of the fetal blood, and only in prolonged and deep anesthetics does anesthetization of the fetal respiratory center occur.

NITROUS OXIDE-OXYGEN

Nitrous oxide-oxygen anesthesia was employed thirty-four times. In one instance the anesthesia was badly taken (or badly given) and death was attributed to its

action. In nine cases bad judgment was shown in its selection as the anesthetic agent.

This form of anesthesia has wide usage and great value. Given by a trained anesthetist the margin of anesthetic safety, while not as great as in the case of ether, is nevertheless ample. During the second stage of labor it may be given for short periods with each labor pain and finally pushed to deep anesthesia for delivery.

It has little effect on the contractility of the uterus and predisposes to postpartum hemorrhage only when insufficient oxygen is administered. The rhythm of labor continues throughout, the patient regaining consciousness quickly between pains. As an agent of anesthesia it is of particular value in the types of delivery in which relaxation of the uterus is neither essential nor desired—cesarean section, forceps and spontaneous delivery. Its use is to be avoided when relaxation of the uterus is essential for safe manipulation; e. g., in decomposition of the breech and internal podalic version. It was in disregard to this rule that bad judgment was shown in the selection of gas for 26 per cent of its administrations; in a number of such instances, rupture of the uterus was discovered at the conclusion of labor.

There appears to be very little idiosyncrasy to gas, although some patients take it much better than others. Since it is necessary in obstetric anesthesia to keep the patient "pink," ether has to be given as a complemental agent more often than in other fields of surgery. It is

of great importance that sufficient oxygen (at least 20 per cent in long anesthetics) be administered with nitrous oxide; otherwise the fetus in utero may suffer from anoxemia during the administration and be born in a state of apnea. Resuscitation in such cases is difficult.

Nitrous oxide and oxygen anesthesia is expensive. Since the apparatus for its administration is rather cumbersome and the services of a trained anesthetist are essential, the method is confined largely to hospital practice, where it occupies an important position.

EMPLOYMENT OF THE GWATHMEY METHOD OF
ETHER-OIL ANESTHESIA

The rectal injection of an ether-oil mixture as described and advocated by Gwathmey was considered as a possible factor in death in three instances and was injudiciously employed in one of seven cases. The circumstances of the three cases were somewhat similar: rather long labor, more than ordinary bleeding during and immediately after the placental stage, a sluggishly contracting uterus, further bleeding and a gradual lapse into shock when the patient was returned to bed. All three deaths might have been avoided by more efficacious treatment of the patient as the symptoms appeared.

The Gwathmey method of anesthesia, while not so popular as it was five years ago, still occupies a place of importance in the obstetric armamentarium. It, like ether anesthesia, has a wide margin of safety if the patient is watched carefully. Its originator intended it as a method of analgesia for use in the first and

TABLE 3.—*Maternal Death Rates from All Other Conditions of Childbirth 1931-1935*

second stages of labor. For this purpose it is comparatively successful. It is only slightly effective as an amnesic.

The ether in the rectal mixture, like ether by inhalation, has a tendency to lessen the frequency and force of uterine contractions. An effort has been made to offset this by the addition of quinine; but even so labor is sometimes prolonged and the postpartum retraction of the uterus impaired. I am of the opinion that its administration increases quite decidedly the hemorrhage during the placental stage and that, if this stage is not carefully supervised, serious postpartum bleeding may occur.

This method is particularly well suited to the long labor of some primigravid patients. Without the morphine, but supplemented with pentobarbital sodium, paraldehyde or chloral, it makes a splendid analgesia for short labors. It is associated with no untoward reactions or constitutional effects on the mother. The ether portion of the technic has only limited effect on the respiration of the new-born child, but the morphine,

if given inadvertently too near the time of delivery, may produce troublesome narcosis of the fetal respiratory center.

CHLOROFORM

Chloroform anesthesia was employed in three patients who died of various causes. It was assumed to play a part in the death of one patient and was injudiciously chosen as an anesthetic agent in a patient with eclampsia.

TABLE 4.—*How Is the Medical Profession Fulfilling Its Responsibilities in the Various Groups of Maternal Deaths? 1931 versus 1935*

	All Maternal Deaths	Maternal Deaths During or 24 Hours After Delivery	All Other Maternal Deaths
Maternal death rate.....	Decrease of 24%	No change	Decrease of 28.9%
Nonpreventable death rate.	Decrease of 48.9%	Decrease of 49.3%	Decrease of 48.6%
Preventable death rate.....	No change (1%)	Increase of 52.5%	Decrease of 11.1%
Death rate from errors in judgment and technic on part of physician.....	Decrease of 9.5%	Increase of 108.5%	Decrease of 41.4%
Proportion of deaths due to errors in judgment and technic on part of physician	Increase of 11.1%	Increase of 107.3%	Decrease of 5.5%

I have used chloroform so few times that I am incompetent to discuss its effects, its advantages or its disadvantages. The English still like their chloroform, either for momentary analgesia or more deeply for obstetric anesthesia. The South has never given up the use of chloroform, although ethylene is now being used with favor in many of the medical centers. One fact is known—the long administration of this agent will cause degeneration of the liver, and when liver damage is already existent, as in preeclampsia, the employment of chloroform is inexcusable.

TABLE 5.—*Amnesics, Analgesics and Anesthetics Employed for Patients Who Died During or Within Twenty-Four Hours After Labor*

Agent Used	Number of Deaths in Which Agent Was Employed	Primary Cause of Death	Possible Cause of Death	Poorly Selected

None	40	0	0	0

* Possibly more; these deaths are being subjected to further study.

SPINAL ANESTHESIA

In four of the maternal deaths spinal anesthesia was administered. It unmistakably caused the death of two of these patients; in a third, death seemed more likely the result of it than of the other factors present. The fourth case was a poor risk for spinal injection.

It is the consensus of enlightened medical opinion that spinal anesthesia is a dangerous anesthetic in obstetric practice. It depresses blood pressure when blood pressure is already low, it relaxes the vascular tree when

the latter is already relaxed, it impairs respiration when a normal respiratory excursion and complete oxygenation of the blood are essential, it necessitates placing the woman in the recumbent position with the head dependent when already the flat level position may be productive of syncope, and it trebles the likelihood of shock when intra-abdominal tension falls with delivery of the fetus.

I can see no reason why one should select spinal anesthesia for an obstetric operation, particularly if one has reviewed the literature on the subject and is familiar with the fearful mortality connected with it. However, now and then there comes a wave of popularity for spinal anesthesia and those physicians who have not experienced, or who do not remember, the fatalities of the last one are caught in its flood.

Contractions of the uterus continue normally under spinal anesthesia and retraction of the uterus follows the expulsion of the fetus and placenta promptly and firmly. The anesthetic, however, interferes with the expulsive action of the abdominal muscles; under its influence the patient never advances spontaneously beyond the first stage of labor. The drug has no effect on the respiratory center of the fetus.

LOCAL ANESTHESIA

Local anesthesia has no detrimental effect on the constitution of the patient or the mechanism of labor. It is the least depressing of all methods and should occupy a more extensive place in obstetric practice than it does at present.

Its action is confined to the tissue in which it is injected. It does not weaken the contractions of the uterus, delay labor or predispose to postpartum hemorrhage. Retraction of the uterus after the third stage and involution during the puerperium approach more nearly the natural than under any other form of anesthetic.

Some years ago I compared the results in a series of fifty primiparas whom I delivered under the routine anesthetics—gas, and gas-ether—with an equal group I delivered with morphine-scopolamine analgesia and infiltration of the perineum with procaine hydrochloride. Episiotomy and immediate perineal repair were performed as a routine in each group. Without going into the details of the study, it may be stated that the lessening of blood loss in the local anesthesia group was amazing, and the rapidity of delivery of the placenta, the quickness of the baby's cry and the smoothness of convalescence were most gratifying.

Because of these advantages, local anesthesia is a method peculiarly well adapted to the situation in which loss of blood, relaxation of the uterus, fall in blood pressure, irritation of the lungs or burden on the heart would be fatal. For this reason its use is indicated in cesarean section for premature separation of the normally implanted placenta, cesarean section in the presence of poorly compensated heart disease, and pulmonary disease. It may also be employed to advantage in the vaginal delivery in cases complicated with heart or pulmonary conditions—morphine analgesia during labor and free infiltration of the perineum at delivery permitting of spontaneous delivery, episiotomy, immediate repair and even low forceps. Gellhorn² has so advocated its use for many years.

In all these conditions the surgeon has the pleasure generally of seeing his patient leave the operating room

in as good condition as she enters it. If an obstetrician learns to use local anesthesia it will stand him in good stead on many an occasion. Five-tenths per cent solution should be employed and it should be injected freely. The method is not sufficiently analgesic for routine use, but it fits the situation perfectly in many complications.

THE BARBITURATES

My records reveal that in six of the eleven deaths in which pentobarbital sodium was used death was attributable to the analgesia—quite evidently in two and quite probably in the other four. In two additional instances the choice of the analgesic method, in view of the patient's pulmonary condition, seemed singularly bad. In the eight instances of amytal administration there were two in which the analgesia was quite possibly the cause of death and two in which the selection of the method seemed injudicious.

While it is difficult to say certainly that the analgesic method was responsible for the fatalities, the evidence is preponderantly in that direction. The suspected cases had these points in common: there was no other factor of enough significance to account for fatality; all the patients succumbed with a peculiar type of cyanosis and respiratory depression, rapid thready pulse and shock without hemorrhage that failed to react to the usual methods of treatment. In several instances the deaths were ascribed to heart failure or to pulmonary embolism. If this was the true diagnosis, it is peculiar that so many instances should have occurred in the barbituric acid group. Of the frequently made diagnosis "pulmonary embolism," Kerr says: "There is little doubt that a considerable number of deaths are attributed to pulmonary embolism which should really be relegated to trauma or shock or both. The diagnosis of embolus is a simple explanation and saves the conscience of the person in attendance."

The barbiturates are presumed to have a fairly wide margin of therapeutic safety. This is said to be the case particularly of pentobarbital sodium.³ The reports of Irving¹ and of Galloway¹ and Daichman¹ reveal no maternal anesthetic death. There seems, however, to be a wide range of susceptibility to the action of the drug. For instance, Galloway describes one case in which 22 grains (1.4 Gm.) of pentobarbital sodium was administered in the course of labor without any apparent effect, and the patient at the conclusion stated that she thought she had had a very hard time. On the other hand, Willcox⁴ emphasizes the importance of peculiar susceptibility to the drug and states that he has seen a number of cases in which sudden collapse, respiratory depression and death from bronchopneumonia occurred when only 3 grains (0.2 Gm.) was administered. He particularly opposes the use of the drug as a preparatory or basal anesthetic.

The symptoms of acute poisoning with the drug, as set forth by Sollmann, are coma, marked fall in blood pressure, depression or even paralysis of respiration, fall in temperature, asphyxial convulsions and failure of response to the stimulants indicated. Apparently the same symptoms occur from a smaller dose of the drug in the patient who has an idiosyncrasy to it.

For their effectiveness in labor the barbiturates depend on the capability to produce forgetfulness (amnesia) and very little on analgesic effect. Their

2. Gellhorn, George: The Advantages of Local Anesthesia in Gynecology and Obstetrics, *J. Missouri M. A.* 32: 143-145 (April) 1935.

action in the former direction is greatly enhanced by the addition of scopolamine. The patient may scream as if in great agony during the course of her labor pains but wake the morning after with no clear recollection of what has taken place. In his analysis of obstetric analgesias, Irving states that he considers no method successful which gives less than 100 per cent amnesia. The factor of relief from pain he considers a minor consideration.

The drugs apparently do not inhibit uterine contractions. Labor continues after the administration of the capsules and seems undelayed. In some instances the pains appear to become more tumultuous and delivery is hastened. While some cases of postpartum hemorrhage have been reported, their occurrence may be coincidental.

The advocates of the method assert that their drug supplants morphine, having none of its disadvantages and many advantages. They state that it does not delay labor, does not narcotize the baby and makes the patient forget the unpleasant experience of childbearing. Several maintain that morphine has no further place in obstetric practice because of its ill effect on fetal respiration.

A great disadvantage of the barbiturates is the restlessness that they produce. Patients under their influence may prove difficult to control. In such a confused and semistuporous state of mind, pain arising from the uterine contractions is misinterpreted and the parturient becomes confused. As the time for actual delivery approaches, the patient may become uncontrollable. Careful surgical preparation and spontaneous delivery under such circumstances is impossible. Usually the patient must be anesthetized with gas or ether and delivery consummated by low or mid forceps. The labor over and the pains dispatched, the patient falls into a deep slumber and remains almost comatose for a number of hours.

The most enthusiastic users of the pentobarbital sodium-scopolamine technic acknowledge that the rate of operative intervention is thereby multiplied many times, that forceps delivery becomes essential in from 40 to 60 per cent of cases. They also emphasize that patients under the influence of pentobarbital sodium must be watched with the closest attention, their care individualized and precautions taken that no injuries occur during the most restless periods. For this reason the method is available for use only in the hospital and can only be a source of grief if undertaken in the home.

Considering these facts, one questions whether pentobarbital sodium-scopolamine amnesia fulfils the requirement of safety. If the patient is in constant danger of injuring or contaminating herself, if her cooperation in the course of labor is utterly lost, if the incidence of operative intervention is multiplied tenfold, if the supervision of the case is transformed from an intelligent conduct of labor into the treatment of drug confusion, one doubts that the effect is worth the reaction that it produces.

Furthermore, a grave danger is added to the situation if labor must be terminated by difficult abdominal or vaginal delivery. The margin of safety in deep barbituric sedation is small, and it may be entirely consumed by further inhalation anesthesia, by obstetric shock or by even a limited amount of postpartum hemorrhage.

It is doubtful whether the barbiturate derivatives will replace morphine, for there is no drug that is more quieting, more restful and more efficacious than the

latter in long labor. This fact is recognized in a recent paper^{1a} in which the author advises the administration of morphine as an antidote to the restlessness induced by the barbiturates.

COMMENT

In reviewing the intrapartum deaths from which these statistics were drawn, one is impressed with the fact that the accoucheur seemed often so bent on getting his patient asleep or her baby delivered that he gave little thought to the outcome of his hasty procedures. When the birth of the child was accomplished he was abruptly confronted with the results. The lacerations gaped, the uterus relaxed, the patient's blood began to flow. The analgesic agent that gave such profound rest narcotized the baby; the material that was to bring the mother forgetfulness of her experience combined with third stage bleeding to produce obstetric shock; the anesthetic that made operative delivery convenient relaxed the uterus and caused postpartum hemorrhage. The situation called for real generalship and, unless it was forthcoming, fatality followed.

Thus does the seamy side of obstetric analgesia present itself. He who employs such methods of deep amnesia and deep analgesia will have it to face and must be prepared to cope with the emergencies it produces. The advocates of certain drugs will complain that the description is overdrawn, yet it is the precise story that appears again and again in the case histories.

What answer then shall be given to the new patient who wants first to know whether the pangs of labor will be eliminated?

First, that one fully sympathizes with her desire for relief and is familiar with, and uses in every labor various methods of attaining that end.

Second, that with due regard for her safety and the success of analgesia one prefers to select at the time of labor the drugs which seem best adapted to the condition present and the type of pain; that what is best for Mrs. Smith is not always best for Mrs. Jones.

Third, that one considers her safety and the safety of her child as paramount issues and that with these thoughts uppermost she will be attended closely during the critical period of labor.

With these assurances in mind and with confidence in her physician, the normal patient will approach her time of delivery with equanimity, accept a moderate and safe degree of analgesia, be comforted by the watchful attendance of her physician, and pass through her delivery in better condition than the mother who is drugged to an unconscious state and whose labor becomes a blank chapter in her life.

SUMMARY

1. Analysis of maternal deaths in Philadelphia for a five year period reveals an improvement in all forms of obstetric practice except that which has to do with the intrapartum period.

2. The physician's share in responsibility for sudden fatality in and after labor has increased a hundred per cent.

3. Methods of obstetric amnesia, analgesia and anesthesia have been considered as possible factors in this unfortunate increase.

4. On the basis of records of death, spinal anesthesia has been condemned as a method of practice, and the barbituric acid derivatives have been found not as free of danger as many reports would indicate.

PIRQUET CUBICLES FOR INFANTS

BELA SCHICK, M.D.
AND
SAMUEL KARELITZ, M.D.
NEW YORK

In planning new children's hospitals we have all tried to replace the old large general ward by small rooms accommodating not more than from one to three children. Glass partitions are generally used between cubicles, so that the children may be easily watched by the centrally located nurse.

In 1928 Pirquet¹ described a new kind of isolation bed for new-born babies and young infants. At first Pirquet constructed a single bed separated from the ward by high glass walls instead of the usual railing. This glass wall could be lifted on one side like a window. Such a single isolated bed functioned very satisfactorily, but it was too expensive. Pirquet later modified his idea and built a combined unit of six small beds separated from one another by high glass walls.

Fig. 1.—Pirquet cubicles.

Each of these bed cubicles could be opened by lifting the "window" (one of the walls) along its frame. This cubicle unit has been in use in the Children's Clinic of Vienna for the past eight years, and the results have been satisfactory.

In the Children's Pavilion at Mount Sinai Hospital we were confronted with the problem of having inadequate isolation for about half of the beds in the ward for infants and children under 3 years of age. After the isolated beds were occupied, infants brought in for admission had to be turned away because of inadequate isolation facilities, even though there may have been empty beds at the time. The expense of building large cubicles was temporarily prohibitive. We therefore wanted to install cubicle units such as described by Pirquet, thus hoping to increase our capacity for young infants and give greater protection to these infants than had hitherto been done against cross infections.²

We decided to have two units of five beds each, which could be attached end to end to form a single

unit of ten beds. Both units were mounted on wheels with a diameter of 15 cm. so that they might easily be moved about. This is particularly desirable because the unit can be rolled to the outdoor porches. The total height of the unit is 180 cm. (fig. 1). Each bed measures 100 by 50 cm. The height of the window is 80 cm. These dimensions were selected in order to facilitate the management of the child by nurse or physician, whether standing or sitting. Each little cubicle has a wire spring on which rests a small mattress covered with a sheet. The mattress is set in at a distance of 75 cm. from the ground. There is a little pillow and, if necessary, a bed cover.

For bottle feeding the window is raised just a little, allowing the nurse, who may sit on a comfortable chair, to put her arm through the opening and hold the nursing bottle. With her other hand she can then lift the pillow and support the child's head and upper part of the body. In this way the nurse's face remains outside the cubicle, separated from the child by the glass window. This makes the wearing of masks unnecessary (fig. 2).

The cubicles are roomy enough to permit the changing of diapers and other clothing. It is for bathing only that each child has to be removed from the cubicle. During its absence the cubicle may be thoroughly cleaned, the bed made and the linen changed. The children seem to be very comfortable in their cubicles. They can look at one another and see much that is going on in the ward. They show all signs of contentment.

The cubicles permit the application of intravenous therapy. The child can be easily bandaged for fixation of the needle in the vein. The support for the container for the fluid or blood to be given is outside the cubicle, suspended on a stand. The rubber tube passes through the slightly raised window. When the child requires oxygen it can be given very easily with the oxygen tank standing outside and the funnel being connected with a rubber tube. If a larger tent is necessary it cannot be installed within the unit. A cubicle could, however, be converted into an oxygen chamber simply by having the cubicle made air tight.³ All other manipulations necessary for therapy, such as injections and infusions, are easily performed within the tent.

The child can easily be observed by anybody without direct contact. The danger of infection from without is reduced because external contact is reduced to the short time necessary for examining and handling the child. Any person who has an infection of the upper respiratory tract is not permitted to handle the child. In case of doubt, a mask is worn or the person is prohibited from contact with the infant. The danger of healthy "carriers" still exists, but even this danger is less since contact with the infant is reduced to a minimum. Before handling the individual child, the nurse or physician must wash her (his) hands.⁴

The questions which we wished answered and which are raised by every one who sees these cubicles for the first time are whether the ventilation in the cubicles is adequate and whether the cubicles are large enough to prevent a child's cough carrying infection from one cubicle to another.

From the Department of Pediatrics, Mount Sinai Hospital.
The photographs of the cubicles were taken by Lusha Nelson and Samuel H. Gottscho.

1. Pirquet, Clemens: *Ztschr. f. d. ges. Krankenhausw.* 24: 741 (Dec. 17) 1928.

2. Mr. and Mrs. A. S. Askin were interested in our need and furnished the necessary funds for these cubicles. We are indebted to them for their interest and generosity.

3. We have just converted one of the cubicles into an oxygen chamber. If necessary, several or all of the cubicles could be converted to oxygen chambers by simple additions.

4. The present status of visiting hours in our wards is very rigid. We believe that with the introduction of these cubicles it will be safe to increase the number of visiting hours, since actual contact of the parent and the patient will not take place and therefore the possibility of introduction of infection should be minimal.

Studies were made to ascertain the condition of temperature and humidity inside and outside the cubicles and to determine whether these cubicles were adequately large to avoid the spread of infection from one to the other (table 1).

These readings were made with a wet and dry bulb thermometer and the humidity was calculated from the temperature readings.

The difference in temperature inside and outside the cubicle never was greater than 6 degrees F. and usually was from 2 to 3 degrees, the higher temperature being inside the cubicle no more often than outside.

The relative humidity usually varied from 2 to 6 per cent but reached from 10 to 12 per cent in some instances. The changes seemed to take place more slowly within the cubicles.

The differences in temperature and humidity were only slightly affected by the presence of infants in the cubicles.

EXPERIMENTS TO DETERMINE THE POSSIBILITY OF SPREADING OF INFECTION FROM ONE CUBICLE TO THE ADJACENT CUBICLES

1. The patient had bronchitis and his cough, after feeding, resulted in a spray of milk hitting the opposite wall of his cubicle as high as 4 inches from the top. A large plate placed in the adjacent cubicle failed to show any spraying after four days.

2. Culture plates were stuck 3, 8 and 12 inches from the top of the window opposite the face of a baby who was ill with nasopharyngitis and otitis media. This child was sneezing but was not coughing much. After three days none of the three culture plates showed any growth.

3. *Bacillus prodigiosus* cultures were spread about one cubicle, Oct. 29, 1935, and culture plates were placed in the other four and some just outside the cubicles. After from twenty-four to forty-eight hours all plates were contaminated with fungoid and bacterial growth but in none except the original plates of *B. prodigiosus* was this organism recovered.

4. On one occasion, Nov. 12, 1935, when three children in cubicles vomited and had fever, the same was true of several children in the ward. One nurse who was taking care of these infants had a cold. Cultures taken from the infants' throats and from this nurse revealed a very similar flora:

Nurse: *Streptococcus haemolyticus* beta, *streptococcus viridans*.

Baby A.: *Streptococcus haemolyticus* beta, *streptococcus viridans*, *Staphylococcus aureus* and *albus* and *Pneumococcus* III.

Baby B.: *Streptococcus haemolyticus* beta, *streptococcus viridans*, *Staphylococcus aureus*.

The observations made by Pirquet and those recorded in our study indicate that the temperature inside and outside the cubicle is practically the same. Apparently the chimney effect produced by the space left between the mattress and the wall of the cubicle permits sufficient exchange of air. The measurement of humidity showed equally satisfactory agreements.

The studies to determine the possibility of spread of infection seemed to point to spread by contact of the personnel with the infants rather than from one infant to another. Our statistics, we believe, bear out this impression.

Fig. 2.—Position of nurse's face outside the window while changing the child's diaper.

Another possible question often raised is that of exposure of the infants in these cubicles to direct sunlight. The ultraviolet rays are certainly excluded by the glass partitions, although the lack of vitamin D can be and is counteracted by administration of a substitute, such as cod liver oil or viosterol. Lack of sunlight is a justifiable objection, but this is not more true of infants in these cubicles than of those in other hos-

pital rooms. We take the children out for mercury vapor lamp treatment. We expect to install an ultra-violet ray lamp which will hang from the ceiling and which can be moved to shine over any infant within these cubicles.

SURVEY OF ADMISSIONS TO CUBICLES

The total admission to cubicles has been eighty-nine cases. The average stay has been twenty days.

In twelve children fourteen attacks of acute infection of the upper respiratory tract developed during their stay in the cubicles. Two of these had two attacks, one with otitis media. Three of these occurred on the same day on which their nurse came down with a cold. In one child thrush developed ten days after admission for pneumonia. One child, admitted with pyloric stenosis, died four days later of what appeared to be aspiration pneumonia. On each of two occasions three children developed diarrhea with fever. The attempt to trace the cause was unsuccessful.

The child who was infected with thrush was in the cubicle adjacent to a baby who had been admitted four days before with pneumonia and thrush.

The proof of the efficiency lies in the practical use of the units. It has already been proved by the results of the cubicles in the Children's Clinic in Vienna, which cover a period of eight years. Our experience is of one year's duration, during which time we admitted eighty-nine children into the cubicles with an average stay of about twenty days. In twelve children fourteen attacks of infection of the upper respiratory tract developed (two had two attacks). In three instances the attacks were traced to a nurse who came down with a cold at the same time. It is of special interest that otitis media developed in only three children in spite of the fact that thirty-five children had been admitted with respiratory infections, including four cases of otitis media.

The installation of the unit permitted us to increase the bed capacity from twenty-six to thirty-two. We substituted ten cubicles for four regular size infants' beds and thus gained room for six additional infants. We intend to remove the three beds still remaining in the open ward and replace them by a new unit of six beds, again increasing our bed capacity. The new unit is therefore a decided space-saving device. The cost of manufacturing both cubicle units (ten beds) was \$850. The manufacturers state that they made no profit on this transaction; cubicles of this size will therefore sell for about \$1,000.⁵

We are convinced that this new cubicle system is not only suitable for general use in infants' wards but is especially fitted for the new-born wards of maternity clinics.

We have long been cognizant of the fact that the open nurseries of our most modern maternity clinics are frequently overcrowded and have little or no means of separating the children from one another. We all have frequently been disturbed by the transmission of different infectious diseases (cutaneous, respiratory and alimentary diseases) when the children were not isolated. Essentially there has been little change in the construction of nurseries. We feel strongly that this condition should and must be remedied, and we feel reasonably certain that the demonstrated isolation unit of Pirquet is a satisfactory and economical step forward in the solution of this problem.

5. Dr. Joseph Turner, director of our hospital, has diminished the size of the structure by removing much of the upper framework.

We believe that an admission or reception ward would be decidedly improved by the addition of such a unit of from three to ten cubicles, according to the requirements of the particular hospital. By the sense of privacy that it imparts, it would diminish the number of examinations by curious individuals and also avoid the unnecessary attention paid to a "cute" baby by individuals not interested in the child for any medical reason.

It is our conviction that these isolation beds are satisfactory for the purpose for which they were intended. The nurses and physicians are very much pleased with the practical handling of the units and the children. It is furthermore our recommendation that these cubicle units be tried in nurseries and reception wards.

BLOOD STUDIES

A REPORT OF 2,728 CASES

E. W. PERNOKIS, M.D.

CHICAGO

My purpose in this paper is to summarize the results obtained from examination of the blood of 2,728 consecutive patients reporting to the blood clinic of the Central Free Dispensary, Rush Medical College, Chicago, from April 1, 1933, to Aug. 1, 1936. During this time 93,148 new patients were admitted to all the various departments of the dispensary, and a total of 704,175 visits were made; 2,728 patients from this total number reported to the blood clinic for examination. Half of the number came because of suspected blood disorder by the attending physician, and the remainder because additional aid was desired for the diagnosis. Special mention is made of the incidence and significance of the blood examinations in the blood dyscrasias and the other disorders encountered. An effort is made to show by illustration that the average of a series of blood count values in any of the groups encountered, excepting polycythemia and leukemia, fails to accentuate and tends to minimize any blood abnormality that may exist. All the cases reporting to the clinic may be grouped for convenience into the following six large classifications:

1. Blood dyscrasias.
2. Anemia from hemorrhage not associated with blood dyscrasia.
3. Infections.
4. Miscellaneous group.
5. Abnormal blood changes without definite clinical diagnosis.
6. Normal blood values without any positive clinical diagnosis.

METHOD

A complete blood count was done on every patient reporting to the clinic. The Dare apparatus was used for routine hemoglobin determinations and the Sahli for checking abnormally low hemoglobin values. Red blood counts were done with Hayem's solution as the diluting fluid and with pipets and chamber which bore the U. S. Bureau of Standards qualifications. A hemoglobin value of 70 per cent or lower and a red cell count below 4,000,000 were considered to represent an anemia.

For white blood count determinations 4 per cent acetic acid colored with methylene blue was used as the diluting fluid, and the pipets and chamber likewise bore

the Bureau of Standards qualifications. White counts above 10,000 were termed leukocytoses while values below 4,000 were termed leukopenias. Blood films for differential counts were made both on glass slides and on cover slips which had been thoroughly cleaned with soap and water and alcohol and passed through the flame. The glass slide method was the more practical for clinic use, though cover slip preparations were made in all the more important cases. Wright's stain was used for routine staining and checks were made with Giemsa and May-Grünwald stains when abnormal blood cells were noted. Two hundred cells were counted on the first differential of all cases and on the subsequent counts of all the pathologic cases, and only 100 cells on the patients on whom no abnormality was noted on the first differential. The Goodpasture stain was used for differentiating the acute myelogenous from the acute lymphatic leukemias. The platelets were counted both by the 4 per cent citrate dilution method and the Fonio magnesium sulfate slide method. Values between 250,000 and 350,000 were considered normal.

were met in states of remission and the low ones in states of relapse. All the patients in this group had an achylia gastrica. The leukopenia during the state of relapse was definite though not marked. Lymphocytosis was not constantly found even in the state of relapse. One patient showed a marked eosinophilia of 64 per cent. The only possible cause for the eosinophilia which could be demonstrated clinically was a mild bronchitis. Search was made for animal parasites but none were found. The one characteristic in all the blood films of the pernicious anemia patients in a state of relapse was macrocytosis. Anisocytosis and poikilocytosis varied greatly. All the patients responded to liver therapy.

Purpura.—Symptomatic purpuric manifestations following acute infections, drug administration, metabolic disbalance and cardiac decompensation were the most common. There were five cases of idiopathic purpura haemorrhagica; two were in children 5 and 8 years of age. Neither of these patients had a palpable spleen but both had typical blood values. One child, in addi-

		Low	40	3,490,000	6,600	31	21	3	0

The reticulocytes were counted with 1 per cent brilliant cresyl blue in absolute alcohol. The coagulation time was done with the capillary pipet and the bleeding time with the filter paper method. The color index was determined from the red count and hemoglobin values. No volume index determinations were made. The degree of anisocytosis, poikilocytosis, macrocytosis, achromia and polychromatophilia were carefully searched for on each smear and recorded in terms of pluses. The terms "lymphocytosis," "monocytosis" and "eosinophilia" were used when found above 35 per cent, 8 per cent and 5 per cent, respectively. Values for normal are those accepted by Naegele. Blood counts were done by two technicians under immediate supervision. Blood counts done by students and others are not included.

BLOOD DYSCRASIAS

There were 185 cases of blood dyscrasias, or 6.5 per cent of the total, divided as in table 1.

Pernicious Anemia.—This was the most common blood dyscrasia encountered. Average values for red cells, white cells and hemoglobin determinations fail to reveal as indicated in table 1 the individual characteristics shown on separate counts. The high values

tion to the purpura, also had epilepsy. The third patient was a girl aged 16 years with acute purpura in whom repeated blood transfusions failed to shorten the bleeding time and who died a few hours following an emergency splenectomy. The fourth patient was 19 years of age with typical blood values and symptoms that are controlled by blood transfusion and intra-muscular liver extract injections. The fifth patient was 50 years of age and had had purpura for twenty years.

Hodgkin's Disease.—One third of the cases presented anemia as a late manifestation. Itching was present in one half of the cases. The only constant blood manifestation was either an absolute or a relative leukocytosis. There was no definite disproportion of the eosinophils or monocytes.

Polycythemia.—All the patients were males. The spleen was palpable in only three; 75 per cent of the patients showed peripheral vascular disease. The white blood counts were increased in fifteen of the seventeen cases. The differential count showed an increase in the polymorphonuclear neutrophil cells.

Leukemias.—Two of the sixteen cases were of the monocytic type with the diagnosis confirmed at autopsy. One patient reported to the clinic because of severe

anemia, in the aleukemic phase, and died in the hospital three weeks later with acute myelogenous leukemia. One patient with myelogenous leukemia in the aleukemic phase had cutaneous manifestations and was referred to the clinic from the skin department. One of the myelogenous leukemia patients had had a splenectomy and complained of more pain over the long bones than did the other patients. There were nine

cases of chronic myelogenous leukemia and three of chronic lymphatic type. With the exception of the cases in the aleukemic phase of the disease, the white blood counts were well above the normal values for leukocytosis. The peroxidase stain, when used, gave less help in the differential diagnosis than we had been led to hope for. Vital staining with the neutral red and janus green failed to aid in the diagnosis of the acute monocytic leukemias, which prior to autopsy were considered from the clinical picture and the morphology of the cells as acute myelogenous leukemias. Anemia was present in some stage of the disease and improved with remissions and increased with relapses.

Suspected Pernicious Anemia.—This group was made up of fifteen patients in whom the blood examinations resembled those of pernicious anemia but the laboratory data were not completed and the diagnosis was therefore uncertain.

Aplastic Anemia.—Four of the eight cases placed in this group showed an aplasia of the bone marrow following severe persistent blood loss. All four responded to treatment. Two of the patients with aplasia of the bone marrow were old and had marked arteriosclerosis and no other demonstrable cause for the aplasia. Two patients with marked hypofunction of the bone marrow had manifestations of pituitary and thyroid dysfunction. There were not in the group any cases that could be termed essential aplastic anemia with a rapid downward course. Though there was bleeding from the gums and nose, none of the patients showed any ulcerations on the gums, palate, tongue or tonsils.

Chlorosis.—In this group there are four patients, all young, adolescent girls with very low hemoglobins, high red blood cell counts and marked achromia of the red cells. All four responded well to iron therapy. This group is of interest in view of the supposed rarity of the disease today.

ANEMIA FROM HEMORRHAGE NOT ASSOCIATED WITH BLOOD DYSCRASIAS

In the group of anemia from hemorrhage not associated with blood dyscrasia there are 208 cases, or 7.5 per cent, of the total, with the following causes and frequency: menorrhagia 120, peptic ulcer 55, bleeding hemorrhoids 24, epistaxis 8. One hundred and eighty of the 208, or 86.5 per cent, showed an anemia; the remainder appeared for examination after they had sufficiently recovered so that anemia was not demonstrable. Twenty-one cases, or 10 per cent, showed a leukocytosis, while forty-six cases, or 22 per cent, showed a lymphocytosis. Monocytosis was encountered in thirteen cases, or 6.2 per cent, and eosinophilia in seven cases, or 3.3 per cent. The failure of average counts to give a satisfactory representation of the variations shown by individuals is manifest in table 2, menorrhagia being used as an example. Since exactly similar observations were obtained with the other diseases in this group, they are not reproduced here.

This group was particularly interesting because of the close similarity between many of these patients and pernicious anemia clinically. One patient with repeated blood loss from bleeding hemorrhoids, to which he had attributed little significance, had been diagnosed as having pernicious anemia and treated accordingly for several months before he entered the clinic. Removal of the hemorrhoids and the administration of iron enabled the patient to return to his work within a month. A woman patient with marked uterine blood loss who had been eating many carrots reported to the clinic as having pernicious anemia. She had the lemon yellow color of the skin and an achylia gastrica but a typical

secondary anemia blood picture. Removal of a large bleeding fibroid and elimination of the carrots from the diet caused complete recovery. In none of these cases was there any macrocytosis present on the stained smear, and the color index was below 1.

INFECTIONS

In the group of infections there were 350 cases, or 12.5 per cent of the total, with the varieties and frequency given in table 3. There are here included conditions which of themselves might not be classified as infections but in cases here tabulated other condi-

tions, such as fever, purulent discharge, local evidence of inflammation, supported their inclusion in this group.

When grouped according to the blood picture but without reference to the specific infection, it was found that anemia was present in 173 cases, or 50 per cent of the total, leukocytosis in ninety-two cases, or 26.3 per cent, lymphocytosis in seventy-six cases, or 21.7 per cent, monocytosis in forty-three cases, or 12.29 per cent, and eosinophilia in twelve cases, or 3.4 per cent of the total. Syphilis is taken as an example for this group for the illustration of high, average and low counts; the other diseases showing similar observations are not recorded in table 4.

From the list of diseases it is evident that the more chronic infections are more frequently seen in the clinic. About 25 per cent of the syphilitic patients were referred to the clinic because of jaundice following antisyphilitic therapy. They showed only a secondary anemia and no characteristic differential manifestations. The group of bronchitis patients did not have any noticeable eosinophilia. The tuberculous patients tended to have a leukocytosis as the outstanding blood manifestation. The intestinal parasites did not have an eosinophilia nor did the two cases of echinococcus cyst that were confirmed by operation. The two cases of tularemia showed no characteristic blood manifestations except the positive complement fixation test.

MISCELLANEOUS

The miscellaneous group constitutes the largest group and is termed miscellaneous for lack of a better term to cover the great variety of diseases that it includes. The diseases of which it consists are given in table 5 in the order of frequency.

When grouped according to the results of blood examination without reference to the specific disease, table 6 illustrates the results.

Arthritis is taken as an example for high, average and low counts from this group (table 7). Averages of all the counts in each of the other disease processes included in this classification fails, as it does in the arthritis group, to illustrate any characteristic change.

The arthritis group, which includes all the varieties, varied much in the blood counts. Many were normal, others showed a severe anemia. One point of interest is shown by the patients with hypertrophic arthritis, who had a tendency to show in the differential an increase in the lymphocytes. The patients with anemia, when treated, showed an improvement in the arthritic symptoms.

In the carcinoma group the patients with carcinoma of the stomach showed the greatest anemia and a leukocytosis. The patients with carcinoma of the esophagus and intestinal tract showed milder anemias and less leukocytosis.

Thyroid disease showed in addition to the anemia a lymphocytosis.

The anemias referred from the obstetric department were the most severe. Thirty of the thirty-seven patients had an achylia and a macrocytic type of anemia and responded to liver therapy, and seven patients had a hypochromic type of anemia which responded to iron therapy.

It is interesting to note that all the thirteen patients with lead poisoning showed increased quantities of lead in the urine, but in none of the thirteen was it possible to obtain an increased number of stippled red cells as would be expected.

ABNORMAL BLOOD CHANGES WITHOUT DEFINITE CLINICAL DIAGNOSIS

There are 152 cases, or 5.5 per cent of the total, which showed definitely abnormal blood changes but in which no definite clinical diagnosis was made. Many of these patients failed to cooperate and did not return to the clinic. The following observations were demonstrated:

Anemia found in eighty-four cases, or 55.2 per cent
Leukocytosis in thirteen cases, or 8.5 per cent
Lymphocytosis in fifty-four cases, or 35.5 per cent
Monocytosis in ten cases, or 6.5 per cent
Eosinophilia in eight cases, or 5.2 per cent

NORMAL BLOOD VALUES WITHOUT ANY POSITIVE CLINICAL DIAGNOSIS

There are in the sixth group 786 cases, or 28.5 per cent, in which no definite blood changes were demonstrated and no clinical disease found. Many of these patients came during the height of the depression with many nervous complaints. They were making an effort to acquire more food and coal and expected the doctor

Low	24	2,650,000	3,500	26	12	1	1

to aid them. Many of the blood counts on these patients were done as a routine to eliminate any underlying pathologic condition before the patient was dismissed from the clinic.

SUMMARY

1. Two thousand seven hundred and twenty-eight cases reported to the blood clinic of the Central Free Dispensary of Rush Medical College, Chicago, during an interval of forty months from April 1, 1933, to Aug. 1, 1936. During this interval 704,175 visits were made to all the various departments of the dispensary.

2. The cases are divided into the following groups:

Blood dyscrasias 185, or 6.5 per cent.

Anemias from hemorrhage 208, or 7.5 per cent.

Infections 350, or 12.5 per cent.

Systemic diseases 1,047, or 38.5 per cent.

Blood changes with undetermined clinical diagnoses 152, or 5.5 per cent.

Normal blood without definite clinical diagnosis 786, or 28.5 per cent.

3. Six and five-tenths per cent of the total number of patients who reported to the clinic showed blood dyscrasias, while the others were sent there by the physician in charge to get aid in making the diagnosis in question.

4. Fifty per cent of the cases with infections and general systemic diseases showed an anemia, while 25 per cent of each group showed a leukocytosis. Lym-

phocytosis was present in 20 per cent of the infections and 25 per cent of the systemic diseases. The monocytes were increased in 12 per cent of the infections and 5 per cent of the systemic diseases, while the eosinophils were increased in 3.4 per cent of the infections and 1.3 per cent of the systemic diseases.

5. There were no cases of agranulocytic angina or acute infectious mononucleosis in the collection.

6. In none of the 100 cases of arthritis in which aminopyrine and phenobarbital had been administered was there a case of leukopenia noted.

7. Averages of the blood counts and differential values in the various groups fail to demonstrate the individual differences seen in separate counts.

DISSECTING ANEURYSM OF THE AORTA

T. E. McGEACHY, M.D.

AND

J. E. PAULLIN, M.D.

Resident in Medicine, Emory Division, Grady Hospital, and Professor of Clinical Medicine, Emory University School of Medicine, Respectively

ATLANTA, GA.

It is a rather striking paradox that the most dramatic of all vascular accidents is seldom recognized antemortem. There have been almost 500 cases dealing with rupture of the aorta reported in the literature, and in only nine¹ instances has a correct antemortem diagnosis been made. Swaine,^{1a} Mager,² Davy and Gates,³ Hirschboeck and Boman,⁴ Moosberger,⁵ Vaughan,⁶ Kellogg and Heald,⁷ White,⁸ and Weiss⁹ are listed as having correctly diagnosed cases. Wyss¹⁰ is said to have diagnosed a case, but it seems from his statement that a saccular aneurysm was suspected rather than a dissecting aneurysm, as is also true in the cases of Osler¹¹ and Finny.¹²

We are reporting three cases in which a correct antemortem diagnosis was made, bringing the total number to twelve, which is far short of those in which a diagnosis could have been made during life. The records of three others are also given in which the diagnosis was not made, in one of which no history was obtainable. This presentation is made in an endeavor to

stimulate interest and thereby raise the number of correct diagnoses to a respectable percentage of the whole.

Dissecting aneurysm of the aorta is an incomplete rupture of the aortic wall wherein the escaping fluid separates the layers of the arterial wall to a variable extent. There is usually a terminal rupture at some distant point, either externally or into the original blood channel. Rarely, spontaneous fibrosis and healing occur without a second rupture.

HISTORY

Nicholls,¹³ as early as 1728 demonstrated the fact that rupture of the inner coat of the aorta could occur without rupture of the outer coat. In 1761 he described a dissecting aneurysm found at autopsy on George II, king of England. The patient died immediately after straining at stool and autopsy revealed a dissecting aneurysm which by pressure had almost occluded the pulmonary artery, causing so much back pressure that the right ventricle burst. Morgagni¹⁴ reported a case in 1769, and in 1798 Lynn¹⁵ published a striking account of a dissecting aneurysm occurring during labor. Laënnec¹⁶ in 1819 is usually given credit for the term "aneurysma dissecans." The first case reported in America was by Pennock¹⁷ in 1838. Swaine^{1a} published the first correct antemortem diagnosis in 1856, and in 1863 Peacock¹⁸ presented his classic review of eighty cases. Reports in the literature from this time forward are too numerous to mention.

INCIDENCE

In a review of the reported cases, dissecting aneurysm is most common between the ages of 40 and 70 years. Males are affected twice as frequently as females. Race does not seem to be an important feature, nor does altitude or climate. A study of autopsy statistics reveals that dissecting aneurysm is found approximately once in 500 autopsies.

CAUSATIVE FACTORS

There are two features necessarily present in almost every dissecting aneurysm. First there must be a defective aortic wall and, second, an abnormal hydrostatic pressure in the aorta. It has been demonstrated that the normal aortic wall will withstand a pressure above 1,000 mm. of mercury. Since this greatly exceeds the pressure reached even during severe hypertension, a pathologic aortic lining must be included as one of the factors. Considerable study has been carried out in this direction, and from the numerous observations that have been made it seems clear that the real causative factor lies in the media. Quite frequently intimal fissures and tears are found without any demonstrable dissections, which would tend to prove that unless the media is readily split there will be no dissecting aneurysm. The only fairly constant finding in the media has been a degenerative change, which results from sclerosis of the vasa vasorum. Whether this causes a loss in the connecting fibers between the laminae of the media has not been definitely settled.

From the Department of Medicine, Emory University School of Medicine.

There have been several cases reported in which there was dissection in the media without any intimal rupture being demonstrated. The fluid filling the cavity was blood from ruptured vasa vasorum, but in one case reported by Whitman and Stein¹⁹ it was "a clear lymphlike fluid." With this pathologic condition present in the media, a pressure within the aorta sufficient to break through the intima is all that is necessary to complete the process. In most cases this force is supplied by the already present hypertension supplemented by an additional rise in pressure due to exertion. This last feature is often "the straw that breaks the camel's back." Congenital hypoplastic aortas, coarctation of the aorta and syphilis are sometimes apparently causative factors, but these make up a small minority of freak cases.

CLINICAL MANIFESTATIONS

Prodromal Symptoms.—Since hypertension is so generally a factor in cases of dissecting aneurysm, it is usually possible to elicit from the patient a history of headache, vertigo, spots before the eyes, gastro-intestinal disturbances, shortness of breath and other manifestations of elevated arterial tension. The patient quite frequently has been told by a physician that he has high blood pressure. In only one case²⁰ have we found preexisting fear of imminent calamity.

Onset.—The onset as a rule is sudden and arresting. The patient, without warning and during exertion, suddenly experiences an agonizing, tearing pain, usually in the anterior portion of the chest, which is so severe that shock immediately follows. This pain, which feels as though something has been "torn loose inside," lasts a variable length of time, usually from ten minutes to two or three hours. It may remain localized in some part of the anterior chest wall, usually the precordium, but more often it radiates to the back in either the thoracic or the lumbar region or to the epigastrium. It is seldom referred to the arms and in those cases in which this radiation is present it is as a rule referred to the outer surface rather than to the inner. In a few cases there is no acute onset but more of a feeling of malaise, symptoms of cardiac insufficiency, occasional precordial or substernal distress; these, however, make up about 10 or 15 per cent of the total number of cases. Patients with the typical onset frequently lose consciousness for several minutes, although some remain perfectly clear mentally. Quite frequently there is a temporary loss of vision and a fear of impending death. Many become nauseated and vomit soon after the onset. Shock is usually present, with cold extremities, clammy perspiration and dyspnea, which usually lasts from twenty to thirty minutes. If the dissection by pressure blocks the subclavian or iliac arteries there is usually a feeling of numbness and weakness in the corresponding extremity with, at times, almost total temporary paralysis. If the carotid artery is involved there may be hemiplegia, convulsions and other symptoms resembling a cerebral hemorrhage.

PHYSICAL SIGNS

Examination of the patient at this time usually reveals the blood pressure above normal in spite of the other signs of shock. The heart is usually enlarged and a systolic murmur at the apex and over the aortic area is generally present. Quite frequently there is a to and

fro aortic murmur suggestive of aortic insufficiency, although the peripheral signs seldom bear this out. The aortic area of dullness is usually somewhat increased. At times, over the course of the aorta, rumbling, hissing or blowing murmurs may be heard, depending on partial occlusion of the aortic lumen from pressure of the dissecting aneurysm. The lungs are usually clear except for congestion at times in the bases and quite frequently a small amount of fluid, especially in the left pleural cavity. Coolness and absence of arterial pulsation in one or more extremities are frequently present and are the most outstanding diagnostic signs. If the occlusion is only partial, the blood pressure may be unequal in corresponding arteries and there may be a blowing systolic murmur at the point of partial block. Deep pressure over the abdominal aorta may at times be quite painful if dissection is present in this vessel. When the dissection involves vessels supplying various segments of the spinal cord, there may be bizarre neurologic manifestations such as loss of reflexes, paresthesias and motor paralysis. Blockage of a carotid artery gives the neurologic picture of a widespread cerebral hemorrhage or embolism.

QUIESCENT STAGE

In a considerable majority of patients there is a stage, following the onset and preceding the terminal collapse, in which the patient is fairly comfortable. The signs of shock disappear and the pain remains only as a dull ache over the areas of radiation.

At times exertion may cause a partial return of the pain but seldom to the severity experienced at the onset. In the extremities wherein arterial pulsation is absent, gangrene does not develop as would occur in true thrombosis or embolism. The extremity merely remains cool with a gradual return of sensation and motion. Owing to slow leakage through the adventitia, more and more fluid may accumulate in the chest, usually on the left side. There may be urinary or digestive complaints if vessels supplying the abdominal organs are involved in the dissection. The patient may have a low grade fever during this stage, seldom reaching 101 F., and at times a subnormal temperature may exist. The physical signs found at the onset remain fairly constant, such as murmurs over the heart and arteries, elevated blood pressure, cardiac enlargement and increase in mediastinal dullness. Occasionally during this period it may be noticed that there is venous distention due to mediastinal blockage. This stage may last from a period of minutes to several years but is usually a matter of days.

Fig. 1.—Appearance of chest in case 1, showing marked cardiac enlargement and increase in mediastinal shadow in first and second interspaces.

TERMINATION

Generally the curtain falls on the third and final act in this clinical drama as suddenly as it rises on the first. The patient is usually resting comfortably and makes some slight movement, such as turning in bed or raising

19. Whitman, R. G., and Stein, H. B.: A Contribution to the Pathogenesis of Dissecting Aneurysms: A Case of Dissecting Mesoarthritis (Babes and Mironescu) Without Dissecting Aneurysm, *J. M. Research* 44: 579-592 (Sept.) 1924

20. Draper, W. H.: Case of Dissecting Aneurysm of the Aorta, with Plugging of the Arteria Innominate, by a Portion of the Internal Coat of the Vessel, and Rupture of the Pericardial Sac, *M. Rec.* 1: 32-33, 1866.

his head, when without warning he gasps for breath or cries out with pain and falls back on his pillow and in two or three minutes is dead. This terminal collapse is evidence of rupture through the outer coat of the aorta, most frequently into the pericardium or, at times, into the left pleura. In rare cases the end comes as a slow and gradual process simulating congestive heart failure or uremia. When reentry occurs into the original lumen

Fig. 2.—Tracing in case 1, January 10. (Figures 2-7 show serial electrocardiograms made each day the patient was in the hospital. The changes observed are probably due to disturbance of the coronary blood flow from dissection of the aneurysm about the coronary arteries.)

of the vessel with the formation of a so-called double aorta, death may not take place for years and then as a result of some intercurrent infection, trauma or other entirely unrelated causes.

LABORATORY OBSERVATIONS

The urinary changes, as a rule, are those consistent with moderate kidney damage; i. e., varying degrees of albuminuria, pyuria, hematuria and cylindruria. There is usually some anemia present, but as to how much of this is due to the dissecting aneurysm and how much is due to the associated nephritis it is yet uncertain. There is present usually a distinct leukocytosis ranging from 9,000 to 30,000 with a relative polymorphonuclear increase. Electrocardiographic studies have been made in only seventeen cases and the results have been rather inconstant; however, left axis deviation and changes in the T waves have been the most constantly observed features.

Roentgenographic features have been carefully studied by Wood, Pendergrass and Ostrum²¹ with the following observations: There is usually a deformity of the supercardiac shadow, which may or may not pulsate under the fluoroscope. This deformity may be an arcuate excrescence arising from any portion of the thoracic aorta. At times a shadow may be seen along an aortic branch, and this is the most pathognomonic of all x-ray appearances. There is at times displacement of the trachea and esophagus, and at times a non-fatal leakage may be evident as a pleural effusion, usually left sided or as a mediastinal infiltration. Cardiac hypertrophy is nearly always present.

Since syphilis is a rarity in these cases, the blood Wassermann reaction is usually negative.

The blood chemical studies are of little value. The chemical constituents are usually within normal limits; in some patients there is a tendency toward a terminal rise of retention products, which is probably due to continued disturbance of the kidney circulation.

DIFFERENTIAL DIAGNOSIS

Coronary occlusion with cardiac infarction is the most confusing condition to differentiate. The sudden, terrific, tearing pain occurring during exertion, characteristic of dissecting aneurysm, is not encountered as a rule in coronary occlusion, in which the development of the pain is somewhat slower and is oppressive rather than rending. Shock accompanies both conditions but is more sudden in dissecting aneurysm. The site of onset of pain may be the same, although usually that in coronary occlusion is fairly low in the chest, beneath the sternum, with radiation to the neck and left inner arm, while the pain in dissecting aneurysm begins high in the chest, behind the sternum, and radiates to the back in either the thoracic or the lumbar region. A pericardial friction rub has not been observed in dissecting aneurysm. The more or less constant electrocardiographic signs in coronary occlusion have not been found in dissecting aneurysm, although changes suggestive of this are reported, as in one of our cases. Definite x-ray appearances in dissecting aneurysm would aid greatly in diagnosis, while blockage in circulation does not occur in coronary thrombosis except as a late embolic phenomenon. Pleural effusion is also very rare in coronary occlusion. Angina pectoris may be quickly discovered by its response to vasodilators, absence of shock and the like.

Saccular aneurysm should present no great difficulty, owing to its relatively insidious onset, erosion of bone and roentgenographic features, even though at times it may give definite circulatory changes. Cardiac hyper-

Fig. 3.—Tracing in case 1, January 11.

trophy is also rare with saccular aneurysm, and there is usually a syphilitic history or positive blood Wassermann reaction.

Cerebral hemorrhage, unless it occurs simultaneously with the dissection, can be ruled out by the absence or diminution in carotid pulsation on one or both sides or at times by spinal puncture.

Spontaneous collapse of the lung may be discovered by careful examination of the chest and the use of the x-rays.

21. Wood, F. C.; Pendergrass, E. P., and Ostrum, H. W.: Dissecting Aneurysm of the Aorta with Special Reference to Its Roentgenographic Features, *Am. J. Roentgenol.* 28: 437-465 (Oct.) 1932.

Pulmonary embolism, with its preceding history of surgery or auricular fibrillation and its extreme and progressive shock and cyanosis, may be ruled out fairly readily.

A mediastinal new growth or abscess which may appear confusing on x-ray examination should be easily distinguished from a purely clinical standpoint as to history and examination.

Fig. 4.—Tracing in case 1, January 12.

The acute abdominal conditions such as ruptured peptic ulcer, cholelithiasis or nephrolithiasis may at times be confusing, especially in the rare type of dissecting aneurysm in which the rupture is in the abdominal aorta. Here only a complete history and examination with especial emphasis on circulatory phenomena may be the means of arriving at a correct conclusion.

REPORT OF CASES

The following cases have not been reported in the literature prior to this time. In the first three it was possible to make a definite antemortem diagnosis, while in the other this condition was not recognized before an autopsy was performed.

CASE 1.—A. H., a Negress, aged 32, a hair dresser, seen at Emory Division of Grady Hospital, Nov. 4, 1929, complained of dimness of vision. Sluggishness of the right pupil and a positive blood Wassermann reaction were the only positive manifestations. She did not return for treatment. She was next seen March 23, 1932, complaining of smothering spells at night and irregular menses. The blood pressure was 200 systolic, 140 diastolic. The retinal vessels were moderately sclerotic, with a few hemorrhages and exudates. X-ray examination of the heart showed moderate enlargement with a normal aortic shadow. The heart sounds were normal except for slight slurring of the aortic second sound. The blood Wassermann reaction was negative. A diagnosis of malignant hypertension was made. One year later the blood pressure was 216 systolic, 140 diastolic and her general condition was much the same. She felt fairly well except for occasional headache and vertigo until Jan. 8, 1935, when at 1:30 p. m., while curling a patron's hair, she had a sudden terrific, stabbing pain beneath the lower third of the sternum. She immediately stopped working and stood motionless, but the pain persisted and seemed to spread to the epigastrium. She was then assisted to a cot and lay still in intense agony. About ten minutes after the onset she was given half a glass of warm salt water, which she vomited at once without relief. About five minutes later the intense substernal pain spread rather rapidly to the

right shoulder and right groin and then involved the entire right arm and leg, and she was unable to move either of these. All this occurred within thirty minutes after the sudden onset. She arrived at the Grady Hospital at 4 o'clock still suffering intense pain beneath the sternum, in the epigastrium and in the right arm and right leg. The right arm and leg could not be moved. She was sweating profusely and complained of being unable to see. She was extremely restless. She was treated in the emergency clinic and then admitted to the medical ward.

Physical examination three hours after onset revealed the following: The blood pressure was 160 systolic, 90 diastolic in the left arm and not obtained in the right. The temperature was 99 F., the pulse 100 and the respiration rate 24. The pain had almost ceased by the time she was placed in bed. The skin was still slightly moist. She complained of being unable to see. The pupils were equal and active. The fundi showed marked retinal arterial sclerosis and a few old exudates. The right carotid artery seemed to pulsate a bit more vigorously than the left. From the subclavian artery on the right throughout the entire upper extremity no arterial pulsation could be felt, while the arteries of the left upper extremity pulsated normally. The right arm felt slightly cooler than the left. There was no palpable suprasternal pulsation. The trachea was in the midline without any tug. The chest appeared symmetrical, and expansion was fair and equal. Over the left base posteriorly there was a slight dullness, diminished whispered voice and breath sounds, and diminished tactile fremitus. Elsewhere the lungs appeared normal.

The apex beat of the heart was 11 cm. to the left of the midline in the fifth interspace. The right border was 3 cm. from the midline in the fourth interspace. The total aortic dullness was 9 cm. No shocks or thrills were present. At the apex the cardiac sounds were of fair muscular quality with a soft short blowing systolic murmur transmitted toward the base. Over the aortic area there was also heard a soft short systolic murmur transmitted slightly toward the neck. The aortic second sound was accentuated and reverberating and was followed by a questionable short diastolic blow.

The abdomen was obese and moderately tender throughout with marked tenderness in the right inguinal region. No

Fig. 5.—Tracing in case 1, January 13.

viscera were felt. No fluid was demonstrated. Arterial pulsation appeared normal throughout the left lower extremity but none was felt in the arteries of the right leg. The blood pressure in the left leg was 170 systolic, 110 diastolic and was not obtained in the right. The skin of the right leg was cooler than that of the left. The right arm and leg could be moved voluntarily with difficulty and appeared weak. Tactile sensation in the right arm and leg was moderately diminished. All reflexes appeared normal except the knee jerk, which was sluggish on the left and absent on the right.

A diagnosis of dissecting aneurysm was made.

For the next few days there was very little change in her condition. She complained of some indefinite epigastric pain. Within twenty-four hours after the onset her vision had returned and after the third day the right arm could be moved, but the right leg remained very weak. The temperature was about 99 F. January 14 the blood pressure in the left arm was 170 systolic, 110 diastolic; no pulsation was palpable in either

Fig. 6.—Tracing in case 1, January 14.

the right brachial, radial or femoral arteries. There was no evidence of gangrene in either extremity and the right limb was 1 degree cooler than the left. Two days later (January 16) the patient complained of feeling very hot and as though she were suffocating. Severe hiccups developed and she died rather suddenly and quietly within five minutes after their onset.

On admission the red blood cells numbered 3,910,000 and the white blood cells 12,000, with 85 per cent polymorphonuclears. The blood chemistry was normal. The urine contained a trace of albumin and numerous fine and coarsely granular casts. The spinal fluid was normal and the blood and spinal fluid Wassermann reactions were negative. January 14 the blood nonprotein nitrogen rose to 250 mg. per hundred cubic centimeters, creatinine 3.0 mg. The sedimentation rate was normal. Blood culture was sterile.

In a roentgenogram of the chest at a distance of 6 feet the heart distance from the midline to the most distant left border was 12.5 cm., the distance from the midline to the most distant right border was 5 cm., the diameter of the thorax was 26 cm., and the maximum aortic shadow was 9 cm.

Autopsy was performed twenty-four hours after death by Dr. Jack C. Norris. The body was well developed and obese; it was examined after it had been embalmed. There was no edema of the extremities, no marked distention of the abdomen and no evidence of external hemorrhage. Examination was limited to the thoracic cavity.

There were numerous fibrinous adhesions between the left lung and the chest wall; the left lung seemed partially collapsed. There was about 200 cc. of blood tinged fluid in the left pleural cavity. The upper mediastinum and about the hilus of the left lung were infiltrated with what appeared to be a partially organized blood clot.

The pericardium contained about 800 cc. of clotted blood. The heart weighed 500 Gm. The heart was definitely enlarged by hypertrophy of the left side; the left ventricular wall measuring 3 cm. in thickness and was otherwise normal.

The aorta measured 4 cm. in circumference, and several slightly elevated yellowish areas were observed that appeared to be early arteriosclerotic changes. The coronary ostia were somewhat narrowed. The wall of the aorta was thinner than normal and the adventitia was loosely connected. There was a transverse rupture about 2.5 cm. above the valve. The blood had descended through the outer third of the media and had escaped down into the pericardial cavity. The dissection

involved almost the entire circumference of the aorta, from the coronary ostia throughout the entire extent of the thoracic aorta, and also involved in the same way the vessels, leaving the aortic arch.

CASE 2.—J. W., a Negro, aged 41, a truck driver, admitted to the medical service of the hospital about 7 a. m., Oct. 25, 1933, stated that he had been entirely well all his life aside from the actual childhood diseases and an occasional attack of urethritis. He arose on the morning of October 25 feeling as usual and was attempting to draw a bucket of water from the well when he suddenly felt a viselike pain beginning at the base of the neck on the right and running, with a tearing sensation, diagonally across the chest to the left nipple, and from there down the left side to the left hip. He felt weak and dizzy and broke into a cold sweat but did not lose consciousness. After sitting down for several minutes he found that the pain had become much less severe and changed to a dull ache over the area of its original radiation. Dyspnea, which appeared at the onset, became much less marked. He later walked to the house and ten or fifteen minutes later ate breakfast and started to work. He walked about two blocks, when he had a second attack of pain exactly as before and in addition his left leg suddenly became numb and gave way under him. He caught at a lamp post to keep from falling and lowered himself to a sitting position on the curbing. His pain continued to be very severe and he was carried by friends to the hospital for treatment.

Physical examination on admission revealed blood pressure of 160 systolic, 94 diastolic in both arms. The temperature was 98.6 F., the pulse 80 and the respiration rate 24. He was complaining of extreme substernal pain and was moderately dyspneic. The pupils were equal and active. The fundi showed only moderate arteriosclerosis. The head and neck were otherwise normal. Expansion of the chest was fair and equal and the lungs were clear and resonant. The cardiac impulse was 10 cm. to the left of the midline in the fifth interspace; the left border of dullness extended 11 cm. in the fifth interspace. The right border of dullness was 4 cm. in the fourth interspace and the aortic dullness in the second interspace was 9 cm. There were no shocks or thrills. The heart sounds were of fair muscular quality and there was a soft systolic murmur at

Fig. 7.—Tracing in case 1, January 15.

the apex transmitted toward the base. The aortic second sound was slightly accentuated. There was definite tenderness in the left lower abdominal quadrant but no mass, thrill or bruit could be demonstrated. There was slight weakness in both arms but the reflexes and arterial pulsations were normal, as were those of the right lower extremity. In the left leg there was a complete loss of arterial pulsation in the femoral and popliteal arteries. The skin of the left leg felt slightly cooler than that of the rest of the body but was not cold and showed no sign of gangrene. There was a loss of superficial sensation

over the foot, ankle and lower half of the left leg. Joint and muscle sense was intact. The patient was able to move his extremity only slightly. The deep reflexes were normal.

On admission the red blood cells numbered 3,920,000, hemoglobin 70 per cent, white blood cells 13,350 with 85 per cent polymorphonuclears; urinalysis revealed specific gravity 1.028 and albumin 3 plus with from 5 to 6 granular casts, from 5 to 6 pus cells, and 1 red blood cell per field. October 27 blood

Fig. 8 (case 1).—Heart and aorta showing the rupture and dissection of the aneurysm.

chemistry showed nonprotein nitrogen 100 and creatinine 1.8 mg. per hundred cubic centimeters. The blood Wassermann reaction was negative. An x-ray film of the chest was made with the patient in bed and revealed a peculiar diffuse widening of the upper mediastinum.

Clinical diagnosis was transverse rupture of the aorta with dissection to and blockage of the left iliac artery by a hematoma.

The temperature rose to 99.8 October 26 and to 100 October 27. The patient complained of occasional attacks of substernal pain but between the paroxysms he was fairly comfortable. The sensation and use of the left leg returned very slightly but no pulsation was observed in the arteries. The only drug given was morphine. At 1 p. m., October 27, he sat up in bed and fell back unconscious and died quietly three minutes later.

Postmortem examination by Dr. Norris revealed a small amount of uncoagulated bloody fluid in both pleural sacs. In the upper mediastinum and around the hilus of both lungs there was a moderately bloody infiltration. The pericardium contained 500 cc. of liquid and coagulated blood. The heart weighed 850 Gm. The valves were normal throughout. The aorta was markedly sclerotic. There was a transverse slit 2.5 cm. above the aortic valves. From this point the blood had dissected back toward the heart and ruptured through the remaining media and adventitia into the pericardium. The dissection distally involved from one half to two thirds of the aortic circumference but was mainly on the posterior part of the media but at times reached the adventitia. The dissection extended downward in the left iliac artery, where it formed a hematoma and almost completely occluded the lumen of the artery. A small quantity of blood had also escaped into the retroperitoneal tissue. The kidneys showed moderate chronic glomerulonephritis.

Anatomic diagnoses were (1) transverse rupture of the aorta with dissection and blockage of the left iliac artery by an intramedial clot, (2) hemopericardium and (3) generalized arteriosclerosis and chronic glomerulonephritis.

CASE 3.—W. E., a Negro, aged 39, the driver of an ice wagon, admitted to the hospital, April 28, 1926, had had measles, whooping cough and smallpox as a child. In 1915 he passed a small renal calculus; in 1918 he had influenza and in 1920 he had typhoid. He had worn glasses for several years because of poor vision but considered himself in perfect health at the onset of the present illness. At noon, April 28, as he stepped into his wagon he had a sudden attack of severe agonizing pain

beneath the upper sternum, which radiated to the right lower quadrant of the abdomen. There was also some radiation to the back and to the right arm. The patient fell in the street and was unable to move for thirty minutes, even though he had been given one-fourth grain (0.016 Gm.) of morphine soon after his collapse. At the end of thirty minutes he felt much better but in attempting to rise found that his right arm and leg were numb and weak. The patient was carried to the hospital and admitted to the surgical service with a diagnosis of renal colic.

On physical examination the patient was well developed, well nourished and robust; he was lying on his back in bed, breathing rapidly and apparently in some pain. The temperature was 97 F., the pulse 60 and the respiration rate 28. The head was essentially normal except for the eyegrounds, in which there was slight haziness of both disks, with moderate sclerosis of the retinal vessels. No hemorrhages or exudates were seen. Both carotid arteries were pulsating vigorously. No venous distention or tracheal tug was present. There was a very slight systolic pulsation seen over the manubrium but it was not palpable. Expansion of the thorax was free and equal. The lungs were clear and resonant throughout except for a slight wheezy prolongation of expiration. The heart was moderately enlarged to the left. The apex impulse in the fifth interspace was 2 cm. outside the midclavicular line; the beat was forceful and thrusting in character. The retromammary dullness was 9 cm. in the first interspace and 8 cm. in the second, more to the left than to the right. Heart sounds were clear and muscular at the apex without murmurs. Over the aortic area there was a blowing to and fro murmur, the systolic phase of which was transmitted well into the vessels of the neck. The blood pressure was 160 systolic, 80 diastolic in both arms. The left femoral artery was pulsating vigorously and there was a systolic thrill and bruit over the left inguinal region. The right femoral artery could be felt, but there was no visible or palpable pulsation; neither was there any pulsation in the other vessels of the right lower extremity, while pulsation in the vessels of the left was easily felt.

The abdomen was flat and symmetrical and held in boardlike rigidity. There was marked generalized tenderness but especially in the right lower quadrant and right inguinal region, where a soft, irregular, tender mass was felt apparently beneath the skin. No abdominal viscera were felt.

In the right lower extremity no deep reflexes were obtained and the skin was cold as far as the upper third of the thigh. No abdominal reflexes were obtained.

The patient continued to have paroxysms of extreme pain radiating over the same areas as his original attack. A diagnosis was made of dissecting aneurysm of the aorta with compression of the right iliac artery. He had a fairly comfortable night (the temperature rose to 100) but at 12:30 p. m., April 29, he complained of sudden terrific pain in the precordium and died in three or four minutes.

The red blood cell count nine hours after admission was 2,090,000. White blood cells on admission numbered 14,140 with 86 per cent polymorphonuclears. The spinal fluid was under slightly increased pressure but was otherwise normal. X-ray films revealed the heart markedly hypertrophied transversely and obliquely. The thoracic aorta was definitely enlarged but no distinct aneurysm was seen. There was no erosion of the vertebra. The blood Wassermann reaction was negative.

Autopsy was performed six hours post mortem by Dr. Norris with the following significant observations: The pericardium was distended with freshly clotted blood, which apparently

Fig. 9 (case 2).—Appearance of the chest.

entered through a rent in the outer coat of the aorta 0.7 cm. long located 1 cm. above the heart. The heart was moderately hypertrophied and firm. No evidence of valvular disease was found. The aorta was the site of only moderate atheroma. There was a transverse rupture of the aorta about 1 cm. above the valve cusps about 3 cm. long and rather stellate in character at one end. Dissection was carried from this point throughout the entire length of the aorta almost entirely surrounding the original lumen. The innominate, left carotid and subclavian and right iliac were also dissected as far as they were observed. Blood had escaped through the intima in the retropleural areas of the thorax and in the upper mediastinum as well as retroperitoneally in the right inguinal region. The kidneys showed a moderate chronic glomerulonephritis.

Anatomic diagnoses were (1) dissecting aneurysm of the aorta, (2) hematompericardium, (3) chronic glomerulonephritis, (4) moderate atheroma of the aorta and moderate generalized arteriosclerosis.

CASE 4.—A white man, aged 54, an executive secretary, had complained of bilious spells for the past eight years. In 1925 he had a nervous breakdown (?) and since that time he had had occasional attacks of substernal pain without radiation. July 15, 1927, he consulted Dr. R. S. Leadingham because of shortness of breath, which had been present for the past six months, as well as dry cough for six weeks and general malaise. About July 2 he had had epigastric discomfort requiring a hypodermic for relief (?). Following this attack he had an irregular low grade fever, paroxysms of coughing and moderate

Fig. 10 (case 2).—Tracing made the second day after onset.

dyspnea but no severe pain. He improved on rest in bed but was still moderately dyspneic and "had never regained his strength."

Physical examination revealed a pulse of 96 and a blood pressure of 140 systolic, 100 diastolic. There were a few moist râles over both lung bases. The apex impulse was diffuse and weak and the left border of dullness was 13.5 cm. in the fifth interspace. There was a blowing systolic murmur at the apex transmitted slightly toward the axilla. The liver was felt two fingerbreadths below the costal margin. There were no eye-ground changes. The blood Wassermann reaction was negative. Analyses of the urine revealed specific gravities of 1.015 and 1.020 with a trace of albumin. Red and white blood cell counts were normal. X-ray examination of the gastro-intestinal tract and the gallbladder gave normal results. X-ray examination of the chest revealed increased density in both bases, the heart diffusely hypertrophied and the aorta normal in size. July 18, an electrocardiogram was reported as showing left ventricular predominance and chronic myocarditis (diffuse). July 23 the patient was placed in the hospital; the blood pressure was 160 systolic, 110 diastolic and the rest of the physical examination as previously given. On rest and small doses of digitalis he improved and he was dismissed August 18, at which time the blood pressure was 138 systolic, 88 diastolic. He returned to work about September 10 and had no further trouble until the morning of October 5, when he arose feeling well and after a normal bowel movement he was seized with a sudden severe substernal pain with radiation to the epigastrium and collapsed. He did not regain consciousness. The pulse could not be felt nor could the blood pressure be obtained; only an occasional heart beat was heard. He died six hours later.

The diagnosis was coronary occlusion. Autopsy revealed the heart moderately hypertrophied. No valvular disease was seen. The myocardium was generally friable but there were no discrete areas of degeneration or of infarction. The aorta contained numerous raised patches of atheroma. At the arch there was a rupture of the intima and from this point for about 15 cm. down the thoracic aorta there was dissection, the cavity being filled with fresh blood. In the right coronary artery there was a small clot that showed beginning organization, but no myocardial change was visible distal to this.

Anatomic diagnoses were (1) dissecting aneurysm of the aorta, (2) cardiac hypertrophy and dilatation, (3) atheromatous aorta and (4) early coronary occlusion.

CASE 5.—J. S., a Negro man, apparently about 40 years of age, was admitted to the medical service in extreme shock. No history was obtained as the patient was brought in by the police, having been found unconscious. The blood pressure was not obtained. The heart sounds were barely audible. Numerous medium moist râles were present throughout both lungs. The skin was cold and clammy. The pulse rate was 48 per minute. The eyegrounds showed marked sclerosis. The urine was negative for sugar. Blood chemistry revealed: nonprotein nitrogen 100, creatinine 3.3, Wassermann reaction negative. Red blood cells numbered 3,500,000, white blood cells 11,650 with 81 per cent polymorphonuclears. A diagnosis of uremia with possible Stokes-Adams syndrome was made. The patient was given various stimulants and fluids but without results. He died quietly eight hours after admission.

On postmortem examination both lungs were found moderately congested. The pericardium was normal. The heart was firm and weighed 500 Gm. The interventricular septum showed numerous old petechial hemorrhages. The aorta showed marked arteriosclerosis. There was a transverse rupture 5 cm. in length 1.5 cm. above the aortic valve. Dissection extended along the posterior aspect of the aorta in the outer media to the third lumbar vertebra. This cavity contained old clotted blood. The intercostal arteries were torn from the original aortic lumen. There were several ulcerated areas in the upper abdominal aorta but no communication with the aneurysmal cavity in this area. There was no external rupture of the aorta. The kidneys showed subacute and chronic glomerulonephritis.

Anatomic diagnoses were: (1) rupture of the aorta with dissecting aneurysm, (2) subacute and chronic glomerulonephritis, (3) generalized arteriosclerosis with marked atheroma of the aorta and (4) chronic myocarditis.

CASE 6.—Mrs. J. B., a white woman, aged 32, was first seen Sept. 18, 1930, at which time she was admitted to the obstetric service with a diagnosis of placenta praevia. She had had four normal deliveries. She last menstruated in May 1930. She felt well until about August 1, at which time she began to have slight shortness of breath, edema of the feet and ankles, and headache. These symptoms grew progressively worse until the night before admission, when she suddenly passed about 1 pint of blood from the vagina. On admission to the hospital she was still passing an occasional dark clot. Blood pressure was 210 systolic, 150 diastolic. No fetal heart sounds were heard or movements felt. The urine contained moderate albumin and innumerable pus cells and a few red blood cells. Numerous moist râles were present over both lung bases. Labor was induced and the patient was delivered of a 3½ pound (1,588 Gm.) stillborn male. She made a rapid recovery and left the hospital September 27 in apparently good condition.

She was readmitted to the medical service November 5, complaining of cough and shortness of breath. She had had intermittent edema of the feet and ankles since her first admission and had a small hemoptysis two days prior to admission. Examination revealed râles over both bases, moderate left sided cardiac hypertrophy with a gallop rhythm, a blood pressure of 180 systolic, 120 diastolic and edema of the feet and ankles. She was put on digitalis and improved rapidly. The specific gravity of the urine was 1.011, with trace of albumin and innumerable pus cells. The basal metabolic rate was plus 19. The blood Wassermann reaction was negative. Chemistry of the blood revealed a nonprotein nitrogen of 33.3 and creatinine of 1.6; red blood cells numbered 3,490,000 with hemoglobin 60 per cent, white blood cells 10,250 with 50 per cent polymorphonuclears. The patient was discharged improved, November 12.

She was not seen again until Aug. 23, 1932, when she was admitted to the obstetric service at 9:45 p. m. She appeared to be about five months pregnant. She stated that she had felt fairly well until about August 15, when she had a cramping spell (?) and since that time had been apprehensive and had spots before her eyes, vertigo and slight shortness of breath. The left arm had felt dead for twelve hours before admission. Examination revealed numerous musical râles over both lungs. The heart seemed in fairly good condition. The blood pressure was 170 systolic, 120 diastolic. Diagnoses of preeclampsia and bronchial asthma were made. The patient seemed to be resting fairly well until about 2 a. m., August 24, at which time she complained of cramping pain in the chest and a choking sensation. She was given $\frac{1}{150}$ grain (0.0004 Gm.) of atropine and seemed to improve slightly. At 5 o'clock she complained of a severe pain in the upper part of the back and she soon went to sleep again. At 6:55 stertorous breathing developed and she died suddenly three minutes later.

Autopsy was performed four hours later and she was found to be seven months pregnant. In the right pleural cavity there was a small amount of pinkish fluid. The pericardial cavity contained 500 cc. of partially clotted blood. The left ventricle was markedly hypertrophied. The aorta was thin, hypoplastic and moderately sclerotic; there was a transverse rupture just above the aortic valves. Dissection was confined to the base of the aorta with an external tear through the adventitia into the pericardial sac. The kidneys showed moderate chronic nephritis.

Anatomic diagnoses were: (1) hypoplastic aorta with moderate arteriosclerosis, (2) transverse rupture of the aorta with hemopericardium, (3) moderate chronic nephritis and (4) pregnancy, seventh month.

SUMMARY OF CASES REPORTED IN THE ENGLISH LITERATURE

Pannhorst²² in 1932 found 133 cases out of 250 in which there were enough data for clinical study. These cases were mainly from the German literature. From the English literature, up to the present date, we have been able to collect 127 cases with clinical data which are presented in the following paragraphs. In a number of these cases important features were omitted, so that the review is to some extent incomplete.

In the 127 cases studied, the age was given in ninety-five. The youngest patient was 17 (Hall) and the oldest 76 years. Two died in the second decade, four in the third, twelve in the fourth, eighteen in the fifth, twenty-seven in the sixth, twenty-four in the seventh, seven in the eighth and one in the ninth.

The sex was given in ninety-three cases, sixty-nine being males and twenty-four females. The race was given in ninety-seven cases, eighty being white and seventeen Negroes.

A history of hypertension was given in sixty cases and exertion at the time of onset was mentioned in thirty-three. Pregnancy was present in six.

Pain was present in eighty cases, substernal in eleven, precordial in thirty-nine, epigastric in fifteen, between the shoulder blades in eleven, lumbar in four, and in the left shoulder in one. The character of the pain in forty-four cases was shooting in eleven, tearing in thirteen, dull in eleven, and viselike in nine. Its duration was minutes in two cases, hours in ten, days in three. Radiation was described in twenty-six cases, epigastric in nine, between the shoulder blades in six, lumbar in six, in the right shoulder in three, and in the left shoulder in two.

Shock was mentioned in forty-four cases and was present five minutes in three, fifteen minutes in four, hours in fifteen and days in one. In twelve cases there was no acute onset.

As associated symptoms there was a temporary loss of vision in eight cases, fainting in thirteen, numbness in the arms or legs in twelve and paralysis in twenty-three, of which twelve were hemiplegias. The right arm was involved in one case, the left arm in one, the right leg in four, the left leg in three, and both legs in two. There was bloody sputum in four, dyspnea in thirty, choking in three, cyanosis in six and gastro-intestinal symptoms (nausea and vomiting) in twenty-two.

Fear of impending death was present in six cases, and in one case this was observed prior to the onset of symptoms.

In forty-four cases there was a period in which the patient was relatively free from symptoms lasting hours in six, days in twenty-nine, months in five, and years in two.

Physical examination revealed fever in thirty-three cases. The pulse was slow and regular in five, slow

Fig. 11 (case 2)—Aorta showing the rupture and the beginning of the dissection.

and irregular in three, fast and regular in nineteen, fast and irregular in four. There was an increase in cardiac dullness in forty-four, with fluid at the right base in three and at the left base in seventeen. A systolic murmur was heard in fourteen, diastolic in two and a to and fro murmur in sixteen. Râles were present in the lung bases in fourteen cases. There was an absence of pulsation in the right carotid in three, left carotid in one, right radial in four, left radial in two, right leg in three, left leg in four. Pulsation was present but diminished in the right arm in three, right leg in one, and both carotids in one. Blood pressure was reported in fifty-two cases and was high in thirty-seven, low in eleven and normal in four.

The urine was studied in twenty-four cases and contained albumin in twenty-one cases, white blood cells in sixteen, casts in fifteen, red blood cells in nine; specific gravity was high in nine and low in five. The blood was examined in thirty-one cases and leukocytosis was present (9,000-31,000) in twenty-nine cases, a

22. Pannhorst, R.: Symptomatology und Diagnose der Aortenruptur und des Aneurysma dissecans, Deutsches Arch. f. klin. med. 175:115-123, 1933.

normal white blood count in two, a normal red blood count in four, and anemia in five.

Electrocardiographic records were obtained in fifteen cases with left axis deviation in eight, and right in one, inverted T_1 in eight, T_2 in three, T_3 in three, myocardial disease in four, auricular fibrillation in two, extrasystoles in five, and one was normal.

X-ray examination was done in twenty-two cases and showed an increased aortic shadow in sixteen, cardiac hypertrophy in nine, pleural effusion in eight and a shadow surrounding a vessel in one.

The location of the intimal rupture was given in seventy-nine cases, ten of which were multiple. The site of rupture was the base of the aorta in forty-two cases, the arch in seventeen, the descending aorta in sixteen and the abdominal in four. Terminal rupture was described in sixty-nine cases, fifty-one of which were into the pericardium, fifteen into left pleura and one each in the right pleura, abdominal cavity and pulmonary artery. There was reentry into the aortic lumen in nine cases and one reentry into the innominate lumen.

The dissection involved only a small portion of the aorta in eleven cases, approximately half of the aorta in thirty-two cases and the entire length of the aorta in thirty-two cases. Syphilitic involvement of the aorta was present in only six cases.

This summary agrees fairly closely with the cases studied by Pannhorst except for his finding eight cases of dysphagia and four cases of extreme thirst. These manifestations were not present in our series of cases.

SUMMARY

Of six patients with dissecting aneurysm of the aorta a correct antemortem diagnosis was made in three; the diagnosis was not made in one patient who was moribund and for whom no history was obtainable on admission to the hospital; in another the diagnosis of coronary occlusion was made and in one other the patient had a complicating pregnancy and eclampsia. It is believed that more correct diagnoses can be made if particular attention is directed to a careful history of the onset and progress of the symptoms with a meticulous physical examination. The x-ray examination is of value as confirmatory evidence and the electrocardiogram may be of some help, particularly if tracings are made each day. An existing hypertension, with perhaps a sudden sharp increase in the arterial pressure, is the provoking cause of rupture in the majority of patients.

1010 Medical Arts Building.

Never Known to Be Late.—During one of his flying trips to America some years ago, as always with engagements innumerable, he took time to go from Baltimore to Boston for the single purpose of seeing a surgical friend with literary tastes who for some months had been bedfast with a decompensated heart; and James Mumford, for it was he, always said that this unannounced visit was what put him on his feet again. I knew of his doing the same thing for an Edinburgh physician of whose illness he heard by chance just as he was leaving the steamer in Liverpool. He was due for an address before the British Medical Association in Oxford, but without hesitation he took the first train to the north and managed to get back to Oxford just in time for the address, blithe and gay as though he had not spent two nights on the train. Indeed he was never known to be late and was somewhat intolerant of tardiness in others.—Cushing, Harvey: *Consecratio Medici and Other Papers*, Boston, Little, Brown & Co., 1928.

MYELOMALACIA WITHOUT THROMBOSIS FOLLOWING INDIRECT TRAUMA (STRAIN)

LEO STONE, M.D.

NEW YORK
AND

HARRY N. ROBACK, M.D., C.M.

TOPEKA, KAN.

The clinical diagnosis of acute transverse myelitis or hematomyelia is frequently made in cases of acute paraplegia or quadriplegia in which at autopsy the cord shows an extensive softening. The myelomalacia may be due to a thrombosis of the anterior spinal artery or to an occlusion of some other vessel or vessels of the spinal cord. Very often there is no microscopic evidence of inflammation or hemorrhage into the cord substance. In many cases the thrombosed vessel is found to be thickened and infiltrated with inflammatory cells, having the appearance of syphilitic arteritis. Most of these cases do not give a history of an injury. However, several cases have been reported of acute paralysis of spinal cord origin due to myelomalacia following a trivial trauma such as a strain. Ornsteen¹ stresses the fact that in diagnosing thrombosis of the anterior spinal artery the absence of direct and violent trauma to the spinal column is of great importance. He emphasizes that the nature of the trauma in thrombosis is not violence but strain, as in lifting or overexertion. Spiller² reports a case in which the first symptoms of paralysis developed within fifteen minutes after the patient had been lifting heavy blocks of ice. At autopsy a thrombotic softening of the cord was found, which was attributed to syphilis. Grinker and Guy³ describe a case in which a boy, aged 15 years, yawned vigorously and stretched his arms upward, outward and then backward, whereupon he suddenly felt a sharp, stinging pain in the lower part of the neck, accompanied by an audible crack. Within twenty minutes all four extremities became paralyzed. At autopsy the entire anterior half of the cord in the lower cervical region was found to be a mass of softening due to thrombosis of the anterior spinal artery. The explanation advanced by the authors is that the fifth cervical vertebra was temporarily luxated, probably compressing the anterior spinal artery, to produce a thrombus from stasis following injury to the vessel wall. We have studied the spinal cord in a case that presented a somewhat similar traumatic history but did not show thrombosis of the spinal arteries:

REPORT OF CASE

History.—A white woman, aged 31, a housewife, had never had any children, apparently because of contraceptive measures. She had always been weak physically. The past medical history was irrelevant except for an anal fistula, which had been operated on twelve years before but which had continued to drain most of the time following the operation. About four months prior to the present illness the patient fell off a porch and fractured her right elbow. This was treated successfully by her physician and then, because of complaints referable to the wrist, a fracture was discovered there also. Some time later the patient complained of considerable pain and limitation of movement in the right shoulder. An x-ray examination of

Read before the Chicago Neurological Society, March 18, 1937.

1. Ornsteen, A. M.: *Thrombosis of the Anterior Spinal Artery*. *Am. J. M. Sc.* 181: 654 (May) 1931.

2. Spiller, W. G., cited by Cadwalader.³

3. Grinker, R. R., and Guy, C. C.: *Sprain of Cervical Spine Causing Thrombosis of Anterior Spinal Artery*. *J. A. M. A.* 88: 1140 (April 9) 1927.

that joint showed no pathologic changes. This complaint, however, persisted and was conspicuous at the time of her immediate illness. There was also slight evidence of atrophy of the small muscles of the right hand which had not been present before the fracture. The patient complained occasionally of slight pain in the interscapular region.

The afternoon of April 19, 1935, while in the yard of her home, the patient pulled herself up by her arms on to the limb of a cherry tree. The day before she had had a very slight "head cold" and some aching in the dorsal spine. While hanging from the limb of the tree she suddenly experienced the onset of numbness and tingling in the right leg. For this reason she let go of the limb and went into the house to bathe immediately, hoping to relieve the peculiar sensation in her leg. After the bath, however, numbness appeared in the left leg also and rapidly spread up the body to the chest. A physician was called at once. On examination, he found some disturbance of sensation but no motor dysfunction. Soon after he left, however, the patient began to suffer bilateral motor paralysis, beginning at the feet and ascending to the chest, until she was unable to move at all. The physician was called again and advised immediate admittance to the Stormont Hospital in Topeka. On admission she had to be catheterized, as she had not voided since the beginning of her illness. The following day one of us (L. S.) was called to see the patient in consultation.

Examination.—The patient was pale and undernourished. Respiration was entirely diaphragmatic, with occasional sighing or gasping respiratory movements. Her arms lay flexed across her chest in a characteristic "cervical cord" position. Both legs

Fig. 1.—Transverse section of most extensively involved area of myelomalacia (hematoxylin-eosin stain).

lay in complete flaccid paraplegia. The sensory level was at the eighth cervical-first dorsal segment on both sides with complete loss of sensation below this level for pain, touch, temperature, vibration and sense of position. The patient could extend her wrists slightly and flex her elbows somewhat. Flexion at the wrists and extension of the arms at the elbow were lost entirely. All movements of the fingers were lost. The reflexes in the upper extremities were hyperactive. When the triceps tendons on both sides were tapped there was a distinct paradoxical flexion of the arm. The abdominal reflexes were not obtained. The knee and ankle jerks in the right leg were slightly depressed. They were deeply depressed in the left leg. On plantar stimulation bilaterally there was an abortive tendency to normal plantar flexion. At times no response was obtained. There was a slight tendency to "equinovarus" position of the left foot. Examination of the cranial nerves gave entirely normal results. There was no gross evidence of Horner's syndrome; cocaine was not instilled. There was slight atrophy of the musculature of the right upper extremity, especially in the small muscles of the hand, and the patient complained of pain on attempted abduction of the right arm. The temperature was 100 F. by rectum; the pulse rate was 88.

Laboratory Studies: The urine was straw colored, and acid, with a specific gravity of 1.005; it was negative for albumin and sugar. Pus was present, from five to ten cells per high power field.

The Wassermann reaction of the blood was negative. Hemoglobin was 79 per cent, red blood cells numbered 3,810,000, and the white blood cells 5,500, of which 80 per cent were polymorphonuclears.

On lumbar puncture the initial pressure was 112 mm. of water; the Queckenstedt test was negative. Cell count revealed

2 lymphocytes. The Pandy test was negative. Total protein was 23 mg. per hundred cubic centimeters and sugar 80 mg. The Wassermann reaction was negative and the colloidal gold test showed all zeros.

X-ray examination of the cervical and dorsal spine showed no evidence of fracture, dislocation, caries or narrowing of the intervertebral spaces.

Course.—The patient was bedridden. During the acute phase her temperature rose to 100.2 or 100.4 F. by rectum each day.

Fig. 2.—Transverse section of lower cervical region of the cord (hematoxylin-eosin stain).

After a few days it did not rise higher than 100 during the period in which she was under observation. Retention of urine persisted and bowel incontinence developed. The sensory level descended gradually to the third dorsal segment. Slight spasticity appeared in the lower extremities. After a few days slight flexion movements of the wrist, extension movements of the elbows and slight flexion movements of the fingers began to appear. Atrophy of the interossei and of other small muscles of the hands developed gradually and symmetrically, however, despite the slight improvement in muscular power. Some respiratory movements of the chest became possible with considerable voluntary effort.

The patient was subjected to lumbar puncture five times following the first puncture, which has already been reported. On puncture two days after the first trial only a few cubic centimeters of clear fluid appeared very slowly. Trauma was not evident in this puncture, but numerous red blood cells were found on microscopic examination. On the day following this a homogeneous bloody fluid was obtained. Two days later, or five days after the initial lumbar puncture, despite the employment of a medium sized needle, manometric pressure was so low that no reading could be obtained. The fluid, however, was clear. On simultaneous bilateral compression of the jugular veins, some rise in the column of fluid occurred but was not sufficient to permit a reading. Three days later the initial pressure was 70. On several attempts no rise in the column of fluid could be obtained with jugular pressure. On one occasion

Fig. 3.—Transverse section of upper thoracic region of the cord (hematoxylin-eosin stain).

it rose slowly to 175 mm. (of water) and then fell promptly on release. Three months later (after the patient had been discharged to her home) the fluid was clear. The initial pressure was 50 mm. (of water). On firm jugular pressure the reading was 235; on light bilateral jugular pressure it was 150; on abdominal pressure the reading was 100. The rise and fall to normal in each instance occurred well within ten seconds. The cell count was 5, the Pandy reaction was negative, and the total protein was 37. The patient was seen by us on a few occasions at her home. Progressively severe sacral decubitus developed and she died ten months after the onset of her acute illness.

Clinical Diagnosis.—From the clinical picture and the course presented by the patient while under our observation two possible diagnoses were given principal consideration: (1) acute ascending myelitis of virus type (?), possibly associated with (inflammatory) hemorrhage; (2) hematomyelia, principally of the cervical enlargement and precipitated by trauma (strain). With this possibility was considered the fact that the bleeding might have occurred in a previously present defect; for instance, a small syrinx. In favor of this concept were the following facts: (1) the anamnestic suggestion that the fractures may have had a neurogenic dystrophic basis, (2) the unexplained arthropathy of the shoulder, and (3) the presence of atrophies, antecedent to the final illness, without other characteristic symptoms (sensory changes, for instance) of a peripheral nerve lesion. It is also noteworthy that the atrophy occurring on the opposite side, following the acute illness, soon became quite symmetrical with the original atrophy.

While continued compression of the cord by any of the elements of the vertebral column could be ruled out by x-ray studies, the possibility of a transitory crush of the cord could

Fig. 4—Islands of gitter cells surrounded by dense glia fibers (van Gieson stain, $\times 80$).

never be entirely excluded. On this basis the possibility of ischemic softening of the cord was considered in this case.

Autopsy.—The examination was limited to the spinal cord. There were no gross pathologic changes in the vertebral column, and the spinal canal was not narrowed at any point. The dura mater was not adherent to the cord at any point. The cervical enlargement of the cord, from about the sixth cervical to the second dorsal segment, was shrunken and felt soft, as though a large portion of the interior of the cord were hollow. A cut surface through the softened area showed a small anterior intact zone, about one fifth of the diameter of the cord, while the posterior four fifths consisted of a cavity in which were contained fragments of soft structureless matter. The area of softening was pale and did not show any evidence either of recent or of old hemorrhage. The left half of the cord appeared more extensively involved in the softening than the right.

Microscopic Examination: Hematoxylin eosin stain of the most extensively softened area at about the eighth cervical vertebra (fig. 1) demonstrated thickened meninges, of which it was impossible to distinguish the pia from the arachnoid. All that remained of the cord substance was a narrow peripheral zone of white matter in the lateral and ventral aspects. The

interior of the cord appeared as a cavity containing numerous isolated fragments of nerve fibers, normal blood vessels and gitter cells. The cavity was bounded anteriorly and laterally by gitter cells and an increased number of small vessels and dorsally by the meninges and some gitter cells. There was no evidence of thrombosis in any of the vessels, none of which contained blood corpuscles. There was a fairly clear demarcation between the intact tissue and the softening, consisting of slightly denser glia tissue, as though some attempt had been made at repair. In the periphery of the destroyed tissue there was an occasional small perivascular collection of lymphocytes, which were reactive to the severe destructive process.

In the section stained by the Spielmeyer iron-hematoxylin method for myelin sheaths, only fragments of myelin could be seen in the ventromedial periphery of the cord. Otherwise there was a complete absence of myelin sheaths. The posterior roots showed some demyelination; the anterior roots were more severely demyelinated. The gitter cells in the scarlet red stain were laden with fat.

In the upper part of the softened area, approximately at the sixth cervical segment (fig. 2), the meninges were thickened, particularly over the posterior aspect of the cord, which was somewhat collapsed. Here the meninges rested directly over the periphery of the cord, thus obliterating the subarachnoid space and gave an appearance as though the meninges had compressed that part of the cord. A few vessels in or near the posterior root showed intimal proliferation; other vessels possessed a proliferated adventitia. At this level the area of softening was less extensive than at the level shown in figure 1 and occupied the entire dorsal half of the cord in addition to a large portion of one anterior column in which the entire gray matter was destroyed. In the intact anterior horn the ganglion cells showed only moderate degeneration in the form of chromatolysis.

In the Spielmeyer stained section there were myelin fragments and some normal sheaths present in the relatively intact areas and especially in the anterior white matter. The posterior roots showed some demyelination, while the anterior roots were fairly well preserved.

In the Bielschowsky silver nitrate stain, nerve fibers, some of which were thickened and fragmented, could be seen in the areas that showed myelin in the Spielmeyer sections. Otherwise there was complete absence of axis cylinders.

The destruction of cord substance in the lower part of the softening, at about the second or third dorsal segment (fig. 3), was less extensive than at the already described levels. In the former the meninges over the dorsal part of the cord were thickened and merged with the destroyed cord tissue, thus obliterating the subarachnoid space. The softening was limited to the dorsal half of the cord, in which there were small cavities that were lined by gitter cells and glia fibers. In certain areas the gitter cells formed islands that were surrounded by dense glia fibers (fig. 4). An occasional vessel in the dorsal root showed moderate proliferation of the intima and adventitia. The anterior spinal artery was collapsed, and not a single vessel contained blood. The anterior half of the cord demonstrated severe degeneration of the anterior horn ganglion cells and degeneration of the descending tracts.

Above and below the limits of softening there was secondary degeneration of the ascending and descending tracts (fig. 5). The areas of secondary degeneration showed a moderate increase of astrocytes (Cajal gold chloride stain), which were progressive in type. In the Holzer stain for glia fibers the glia fibrosis appeared only moderate in degree.

It should be emphasized that the intimal and adventitial proliferation mentioned were both rare and slight. Neither encroached materially on the lumen of any vessel. The change was definitely of secondary or reactive type, a sequel of the myelomalacia. It should also be noted that the vessels in the regions of the cord which were not softened contained blood in contrast to those in the softened segments.

COMMENT

This case is of special interest because of (1) its definite relationship with mechanical strain and (2) the unclear and stimulating problem of its precise patho-

genesis. The strain suffered in this instance was of course not one that would ordinarily cause serious consequences, and this in itself raises the question of antecedent vascular or neural defect or concomitant infection. The postmortem conditions do not provide a basis for consideration of a specific antecedent defect, although certain clinical features (previously mentioned) suggested this strongly. We knew only that the patient was frail and anemic and that she had a chronic anal fistula.

No evidence of syphilis could be demonstrated, nor was there definite evidence of other vascular disease. There was furthermore no evidence of venous or arterial thrombosis. Venous thrombosis in myelomalacia has been emphasized by Mon-Fah Chung.⁴ Arterial thrombosis, especially of the anterior spinal system, has been either demonstrated or assumed to be the cause in most cases of myelomalacia.⁵ It is noteworthy that the second case of Basso and Hassin⁶ presented massive extensive softening of the cord without evidence of thrombosis. These authors mention the possibility of virus infection as an etiologic agent. One cannot conclusively exclude such a possibility in our case, in view of the clinical course, although the late anatomic changes offer no evidence of infection. It should be stated that the myelomalacia was (objectively) of characteristic ischemic type. We cannot of course exclude with finality the possibility of ischemia due to syphilitic involvement confined to the origins of blood vessels at the aorta, as mentioned by Winkelman.⁷ Toxemia of syphilis⁸ we consider an untenable concept in cases in which there is no definite clinical or postmortem evidence of syphilis.

Several authors emphasize the greater delicacy of the posterior spinal vessels as compared with the anterior spinal vessels. Zeitlin and Lichtenstein,⁹ however, point out their relatively lower vulnerability on the basis of rich anastomoses. It should be pointed out that the clinical syndrome presented by this patient was not that of the anterior spinal artery alone but rather a "transverse" syndrome, and that anatomically the destruction of the posterior half of the cord is more nearly complete than that of the anterior half.

The blood supply of the spinal cord has been described and reviewed by several authors,⁹ so that we may confine ourselves to the immediate applications of the anatomic facts. While there is still no agreement as to the precise details, it is generally accepted that, although the anterior spinal artery and the dorsal spinal arteries, both derived from the vertebral arteries, furnish the principal blood supply of the upper cervical cord, a change occurs at about the fifth cervical segment, so that the continuation of the anterior median artery and perhaps the dorsal spinal arteries becomes critically dependent on the reinforcement by the lateral spinal arteries (anterior and dorsal root branches).

These enter through the intervertebral foramina and are described as being derived from branches of the subclavian down to the second dorsal root¹⁰ and below that from segmental branches of the aorta.

It is noteworthy that in addition to the hazard of entry of the lateral spinal arteries by way of the intervertebral foramina, in an especially mobile portion of the spine,¹¹ the trunks from which these are derived pursue devious courses in the neck,¹² in which excessive compression and angulation might occur. The posture which our patient assumed was such that the whole subclavian system might be thrown out of normal alignment. We think therefore that, in a generally delicate and possibly definitely vulnerable individual (this factor uncertain), acute ischemia may have occurred on the basis of compression, angulation or even laceration of the lateral spinal arteries or their parent trunks.

Fig. 5.—Transverse section (A) of lower medulla showing demyelination of ascending tracts, and (B) of lower thoracic region showing demyelination of descending tracts (Spielmeier stain).

SUMMARY AND CONCLUSIONS

In a case of myelomalacia without spinal artery thrombosis and without definite spinal artery disease, symptoms began while the patient was hanging by her arms from the limb of a tree. The myelomalacia may have been precipitated by ischemia due to injury to the cervical lateral spinal arteries or their arteries of origin.

Reports of myelomalacia following slight or indirect trauma such as strain are not common. We suggest that such cases receive especially intensive clinical and anatomic study, that complete autopsies be performed when possible, and that the vascular supply of the regions affected be dissected out up to the origins of the segmental arteries. This alone would settle conclusively some of the problems involved in this subject.

SQUAMOUS EPITHELIAL BONE CYSTS
OF THE TERMINAL PHALANX

AND BENIGN SUBUNGUAL SQUAMOUS EPITHELIAL
TUMOR OF THE FINGER

ARTHUR D. BISSELL, M.D.
AND
ALEXANDER BRUNSCHWIG, M.D.
CHICAGO

Squamous epithelial cysts in the subcutaneous tissues of the hands have been repeatedly described in the literature.¹ It is generally stated that such cysts are of traumatic origin and are due to proliferation of a small fragment of cutaneous epithelium that is carried into the deeper tissues. Wörz,² however, reviewed a series of fifty-five cases and was able to find in only twenty-four of them an adequate history of trauma.

Fig. 1 (case 1).—A, unilocular squamous epithelial cyst in proximal half of distal phalanx. B, appearance taken eight months after operation, showing healed lesion.

That such epithelial cysts not only occur in the soft tissues but may also extensively involve the phalanges is shown by reports in the literature, summarized in the accompanying table.

To this series may be added the following two cases:
CASE 1.³—A girl, whose age is not given, caught her finger in a door in 1917; seven years later, in 1924, the finger presented a swelling of the terminal phalanx. A roentgenogram (fig. 1 A)

From the Department of Surgery and the Division of Roentgenology of the Department of Medicine, the University of Chicago.
1. Behrens, Adolf: Ueber traumatische Epithelcysten, Virchows Arch. f. path. Anat. 250: 145-151, 1931.
2. Wörz: Ueber traumatische Epithelcysten, Beitr. f. klin. Chir. 18: 753, 1897.
3. Patient of Dr. James T. Case, Chicago.

revealed a rounded, well circumscribed, expanding cystic lesion in the proximal half of the terminal phalanx. At operation this was exposed and curetted. Histologic study of the cyst revealed a squamous epithelial lining surrounding laminated keratin. There were no hair follicles or sebaceous glands. Roentgenograms taken several months after operation showed filling in of the lesion by cancellous bone (fig. 1 B).

CASE 2.—A man, aged 41, admitted to the University of Chicago Clinics in May 1936, had had the nail of the left index finger torn off by a revolving fan blade ten years previously. The nail reformed and there were no symptoms until 1935, when a gradual swelling of the terminal portion of the finger developed with slight tenderness on pressure. There was no impairment of function. Roentgen examination (fig. 2) revealed an expanding cystic lesion replacing all but the base of the terminal phalanx. Operation was performed May 21, the palmar aspect of the distal phalanx being exposed through an "alligator bill"

Fig. 2 (case 2).—Anteroposterior and lateral views of index finger showing squamous epithelial cyst involving distal phalanx.

incision. A whitish cystic mass about 1.5 cm. in its longest diameter was found. This was peeled away from the thin dorsal shell and base of the phalanx; closure of the wound occurred after hemostasis, without drainage.

Reports of Bone Cysts of the Terminal Phalanx in the Literature

Author	Age	Sex	History and Symptoms	Roentgenograms	Treatment	Histopathology
Harris, R. I.: J. Bone & Joint Surg. 12: 647, 1930	Adult	♂	Golfer: sudden sharp pain in thumb followed by tenderness on pressure for four years; swelling of distal phalanx progressive with increased tenderness during fifth year; no definite trauma at any time	Destructive, cystic lesion of distal half of terminal phalanx	Excision of a cyst	Fibrous cyst wall lined by squamous epithelium; cyst filled with keratin
Behrens, ¹ 1931.....	29	♂	Hand grenade wound in right 5th digit in 1918; complete healing; 1923 same digit struck by hammer with splintering of nail; pain and sensation of heat for 6 years; also swelling of distal phalanx	None reported	Amputation of distal phalanx of 5th digit in 1929	Squamous epithelial cyst within phalanx just beneath nail bed, producing a circumscribed area of bone destruction
Behrens, ¹ 1931.....	13	♂	Gradual swelling of distal phalanx of left index finger during one year; questionable onset from slight contusion to this finger; no pain	Expanding cystic lesion involving whole of distal phalanx except for small margin at the base	Curettage?	Cyst filled with sebaceous-like material and lined in part by squamous epithelium; where this was missing there was a layer of infiltrated fibrous tissue also containing foreign body giant cells (rupture in situ of cyst?)
Curtis, F. E., and Owen, C. I.: J. Bone & Joint Surg. 15: 998, 1933	29	♂	Swelling of distal phalanx left third finger 1921 accompanied by sense of heat, throbbing pain and tenderness; partial excision of a cyst in 1924 with little relief; continued swelling until 1929	Two confluent cystic lesions destroying all but the base of the distal phalanx	Excision of cysts in 1929	Cyst walls composed of fibrous tissue lined by squamous epithelium; the cysts containing sebaceous material

When the cyst was opened a viscous, whitish, syrupy fluid escaped, leaving denser flakes of sebaceous-like material adherent to the inner walls. Microscopic study of the wall showed it to be lined with a thin layer of stratified squamous epithelium. There were no hair follicles or sebaceous glands (fig. 3).

COMMENT

In four of the six cases there was a history of trauma to the distal portion of the finger in which the cysts subsequently developed. The fact that sebaceous glands and hair follicles were not observed in the lining in any case is evidence favoring the view that traumatic deep implantation of a fragment of cutaneous epithelium is a more probable etiologic factor than displaced embryonic rests, or that these tumors are dermoids.

That masses of epithelium implanted in the soft tissues adjacent to bone may also invade the bone is shown by case 3:

CASE 3.—A man, aged 59, was observed in the University of Chicago Clinics in whom several months following a contusion to the distal portion of the left thumb a firm subcutaneous nodule developed, extending forward from the free margin of the thumb nail.

Roentgen examination (fig. 4) showed a concave erosion of the lateral phalangeal margin. At operation a small round mass partially embedded in bone was removed, together with a thin layer of the adjacent bone. Histologic examination (fig. 5) showed the mass to be composed of squamous epithelium, the central portion of which was beginning to undergo marked keratinization, with suggestion of beginning cyst formation.

This case is cited also because it may illustrate an early stage in the development of traumatic squamous epithelial cysts of bone.

Nonmalignant stratified squamous epithelium may invade bone under other circumstances: 1. The squamous epithelial lining of dentigerous cysts is the result of downgrowth of gingival mucosa along the sinuses, sometimes present between the gingival surface and the cyst cavity.⁴ 2. Chronic osteomyelitic cavities in the long bones may become partially or completely lined by downgrowth of the cutaneous epithelium along the draining sinuses.⁵ In tuberculosis of the calvarium, small cavities within the diploe may present an epithelial lining, also the result of downgrowth of the cutaneous epithelium of the scalp along open sinuses.⁶

From a review of the foregoing cases the following clinicopathologic entity may be described:

Traumatism to the distal portions of the fingers may be followed shortly or after a prolonged period by progressive, slightly or markedly tender diffuse swelling of the distal phalanx without other evidence of infection. Also, such symptoms may develop in the absence of a history of trauma. Roentgenograms reveal a central expanding cystic lesion of the terminal phalanx that has destroyed a portion or almost all of the bone. The clinical diagnosis might usually be chondroma of the phalanx, since experience has shown that these roentgenographic changes are in most instances due to such neoplasms. At operation a cyst is found that is easily peeled away from the surrounding bone. This cyst contains sebaceous material and is lined by squamous epithelium. The lesions are benign, but it is conceivable that recurrences may develop if removal is incomplete. Preoperative clinical and roentgenographic differentiation of these lesions from other processes such as solitary bone cyst, giant cell tumor or chondroma, all of which may produce a unilocular cystic lesion in the bone, is not possible.

Fig. 4 (case 3).—Terminal phalanx of thumb showing concave erosion of bone produced by a small mass of squamous epithelial cells.

Fig. 3 (case 2).—Squamous epithelial lining of cyst in distal phalanx of index finger. Slightly reduced from a photomicrograph with a magnification of 340 diameters.

Fig. 5 (case 3).—Mass of squamous epithelial cells that produced the erosion of bone shown in figure 4. There is evidence of beginning cyst formation in the central portion of the mass. Slightly reduced from a photomicrograph with a magnification of 23 diameters.

CONCLUSIONS

Benign squamous epithelial cysts of bone, probably of traumatic origin but possibly the result of faulty development, occur in the terminal phalanges of the fingers. Their roentgenographic appearance is similar to that usually produced by chondromas. The treatment is surgical excision. This is followed by regrowth of cancellous bone to fill the defect.

4. Grawitz, P., quoted by Morehead, F. B., and Dewey, K. W.: Pathology of the Mouth, Philadelphia, W. B. Saunders Company, 1925, p. 439.

5. Brunschwig, Alexander: Epithelization of Chronic Osteomyelitic Cavities, Surg., Gynec. & Obst. 52: 759 (March) 1931.

6. Erdheim, J.: Ueber Tuberculose des Schädels, Virchows Arch. f. path. Anat. 282: 354, 1932.

As far as we have been able to determine, only four cases have been previously cited in the literature. Two additional cases are here recorded.

In addition, a case of subungual benign squamous cell "tumor" of the finger is reported in which the phalanx was secondarily eroded.

Clinical Notes, Suggestions and New Instruments

ECHINOCOCCUS CYST OF KIDNEY

JOSEPH TENENBAUM, M.D., NEW YORK

Hydatid disease of the kidney is rare in this country. Approximately thirty cases have been reported from the United States.¹ The rarity of this condition, the difficulty of diagnosis and the grave postoperative complications make this report of general interest.

REPORT OF CASE

History.—B. P., a white man, aged 31, born in Russia and raised in Buenos Aires, Argentina, has been living in New York State for the last thirteen years. Neither his parents nor he himself was ever engaged in farming or cattle raising activities. He has had no venereal disease and no serious ailments. His present complaint dates back seven years, when he began to experience pain in the right kidney region, with spells of vomiting, nausea and occasional hematuria. These attacks recurred at intervals of every few months to a year, followed by discharge of "bubbles" and shreds in the urine. He consulted me in October 1933, at which time physical examination,

Fig. 1.—Retrograde pyelogram of the right kidney.

urinalysis, roentgenography and cystoscopy failed to show any definite pathologic changes. Following cystoscopy he felt fairly comfortable until September 1935, when an extremely severe attack brought him back to the office with a specimen of urine filled with long curly shreds and bands of tissue, giving the impression of exfoliated pieces of mucous membrane. A freshly voided specimen of urine was clear and, except for a trace of albumin and a few red and white blood cells, contained no

pathologic elements. Microscopic examination of the shreds previously mentioned was inconclusive. He was admitted to Beth Israel Hospital October 30.

Examination.—On physical examination he was well nourished and of an athletic physique, and presented no noticeable abnormalities. Neither kidney could be palpated, nor could pain be elicited on percussion. Repeated urinalysis failed to add any new information. The blood count revealed 4,780,000 erythrocytes, 12,000 leukocytes, 72 per cent polymorphonuclears, 28 per cent mononuclears and 1 per cent eosinophils; the hemoglobin index was 92 per cent. The Wassermann reaction of the blood was negative. On cystoscopy the bladder was found normal, and both ureters were readily catheterized. Intravenous indigo carmine returned in six minutes in good concentration from each kidney. The right renal specimen contained many pus cells, single and clumped. Pyelography (fig. 1) revealed a dilated, bifid right renal pelvis, and dilatation of the middle portion of the right ureter; the upper calices appeared irregularly diffused and shaggy and had a moth-eaten appearance suggestive of solitary cyst of the upper pole of the kidney.

In view of the uncertain diagnosis and long history of the case, operation seemed indicated, and November 2, under general anesthesia, the kidney was exposed through the extraperitoneal route. The lower pole of the kidney was easily delivered, but the upper pole merged with a dense mass with no definite line of cleavage. During manipulation the mass was torn into, and the operative field was flooded with a gush of fluid and innumerable larger and smaller cysts, characteristic of hydatid disease. After thorough suction and removal of cysts, the kidney and as much of the sac as could be secured without injury to the adjacent structures were removed, ample provision being made for drainage.

Course.—The postoperative course was extremely stormy. Within eighteen hours after operation the temperature rose to 105 F., the pulse to from 150 to 170, and the respiration rate to 36. The second postoperative day brought symptoms of deep shock with onset of extreme restlessness and labored respiration, which at times went down as low as 7 per minute. The patient remained stuporous for the next five days. The skin was covered with an eruption of the erythema multiforme type, with ulcerative lesions on the mucous membranes of the nose, mouth and pharynx. He had difficulty in swallowing for some time after regaining consciousness. Two weeks later two large abscesses developed, one on an upper and one on a lower extremity, which had to be incised and drained. The suture line broke down on the tenth day and several large cysts were drained from the lumbar wound, the largest one measuring 7 by 5 cm.; the last cyst, macerated and without the presence of scolices, was discharged about four weeks following operation. December 1 the wound was resutured, and on Jan. 2, 1936, the patient left the hospital with a small sinus draining serous fluid, which closed within three weeks. The serum precipitation test with echinococcus fluid (Ghedini) and the intradermal test (Casoni) repeated before the patient's discharge from the hospital were strongly positive.

Pathologic Examination.—The right kidney was rather large, with many adhesions attached to the capsule. The capsule, which was thickened, was pulled off with difficulty. The kidney appeared incomplete, its upper fifth being supplanted by a torn cyst. Only about one fourth of the cyst wall was preserved. The cyst wall had an average thickness of 2 mm. Its inner surface had many irregular folds and groves. Its inside was mostly yellowish. The bed of the cyst in the kidney tissue appeared smooth and clean. The kidney measured 10 by 6 by 3 cm. The surface was smooth. The much distended kidney surface formed a thin-walled sac, which continued into the much distended calices. Its inside was deeply hyperemic and a thin-walled cyst 1 cm. in diameter was loosely attached to its inside. The whole specimen was fixed (fig. 2). There were a number of characteristic cysts, all of which were torn. Their original size could not be guessed. There were a number of thin-walled cysts; two of them measured 2.5 cm. in diameter, one 2 cm., one 1.5 cm., and several were smaller. They appeared mostly glassy, partly opaque and grayish from

1. Hinman, Frank: *The Principles and Practice of Urology*. Philadelphia, W. B. Saunders Company, 1935, p. 628.

the outside. They contained rather thin colorless fluid. There were a few torn pieces of obviously larger and more thick-walled cysts.

Microscopic Examination.—In the sediment from the contents of the smaller cysts, hooks and scolices were found. The sections from the cyst walls gave the characteristic laminated structure. Scolices were found inside the wall. The wall of the large cyst at the upper pole of the kidney consisted of

Fig. 2.—Postoperative specimen of right kidney, cyst wall and cysts.

hyaline, partly inflamed tissue. The adjoining kidney tissue was atrophic and chronically inflamed.

The diagnosis was echinococcus at the upper pole of the kidney.

COMMENT

Hydatid disease represents the larval or cystic stage of *Taenia echinococcus*, which in the mature stage is found in the small intestine of the dog, wolf, cat and other carnivora. In common with cattle, sheep, horses and other herbivora, man shares the function of intermediary host through ingestion of parasitic ova passed on with the feces from an infested primary host (commonly the dog). The larva liberated in the process of digestion is carried through the portal venous system to the liver (the most common location of hydatid cyst), thence less commonly to the lungs and, if not arrested before it reaches the left ventricle, it may be swept through the circulation into any other part of the body, including the cortex of the kidney. Echinococcus of the kidney is found in about 2 per cent of the cases of hydatid disease.

It takes approximately fifteen to twenty years for the development of a full-sized echinococcus cyst, and as long as there is no communication with the pelvis (closed cyst) there are no early symptoms except such as may be caused later through pressure, displacement and destruction of the kidney substance associated with hydronephrosis. In time, especially in the presence of infection, the tissues of the hydronephrotic pelvis adjacent to the sac may yield to pressure, establishing free communication for spontaneous evacuation of the cystic contents (spontaneous cure). More often, as in our case, after spilling some of its contents, the communicating rent may become sealed and the sac refilled with daughter cysts (fractional evacuation). This process may be repeated from time to time, accompanied by renal colic due to passage of the daughter cysts through the ureters and occasionally hematuria.² There are two other eventualities of cyst involution: one caused by the slow leakage and absorption of the echinococcus fluid, with consecutive degeneration and calcification of the cyst (a process similar to autonephrectomy in renal tuberculosis³), or the cyst may rupture extrarenally, spilling its contents into the perirenal space and peritoneal sac (hydatid peritonitis). There is also the danger of metastatic secondary echinococ-

cosis "due to a rupture of a fertile simple cyst into the heart or venous system,"⁴ all of which emphasize the importance of early diagnosis.

DIAGNOSIS

The diagnosis of renal echinococcus, especially in the earlier stages, meets with difficulty. The subjective symptoms complained of are dull pain, backache, a sense of heaviness in the upper quadrant of the abdomen and, in the fractional evacuation type, severe renal colics followed by the appearance of "grape" skins or large laminated shreds in the urine. Cystoscopy and functional tests are commonly of little diagnostic value. Plain roentgenograms of the genito-urinary tract may or may not show the presence of a large mass in the kidney region, but pyelography rarely fails to demonstrate some degree of hydronephrosis, compression or displacement, irregularity or the moth-eaten appearance of one or more calices, and in the colicky type some degree of dilatation of the ureter. Microscopic examination of the laminated membrane, the discovery of scolices in the urine, and the positive Casoni and Ghedini tests are pathognomonic for hydatid disease.

SUMMARY AND CONCLUSIONS

1. In an operative case of renal echinococcus cyst there were obscure preoperative syndromes and a grave postoperative reaction.
2. Early diagnosis is important, to guard against the possibility of grave complications arising from infection and rupture of an unrecognized cyst.
3. Of equal importance is the choice of the proper operative procedure: aspiration of half the contents of the sac, followed by injection of 10 per cent solution of formaldehyde, or absolute alcohol, marsupialization of the sac and similar measures in order to prevent the always grave and occasional fatal anaphylactic shock following absorption of hydatid fluid.
4. While with the development of the public water supply and slaughterhouse sanitation echinococcus infestation has been rare in this country, there is ground to believe that, with the development of the wool growing industry now in progress in the United States and Canada, hydatid disease will be on the increase in both these countries.

BILATERAL ORBITAL GRANULOMA

JOHN F. TOWNSEND, M.D., CHARLESTON, S. C.

Tumors of the optic nerve, while not extremely rare, seldom attain the size of the ones reported in this case. These, in addition, are bilateral. The three previously recorded of about the size of those here presented were diagnosed neurofibroma.

David Verner, a Negro, aged 21, admitted to the Roper Hospital Oct. 18, 1934, suffered a burn of the left eye, with no impairment of vision in 1918. The details of this accident were not given, but the patient was quite definite about the year in which it occurred and also about the dates of the stages of the progress that followed.

In 1921 the left eye "began to grow." In 1922 "growth" commenced in the right eye, and both eyes became progressively exophthalmic from that date. Loss of vision occurred in 1924 in the left eye, which was first affected. That was six years after the burn and three years after the commencement of the exophthalmos. Two years later, in 1926, the vision was lost in the right eye also; that was four years after exophthalmos began in that eye.

Up to 1926 the exophthalmos was not great, but an exact description of the size of the eyes at that time could not be obtained. Since that time, during the eight years that elapsed before he presented himself for admission, the enlargement proceeded more rapidly. Both orbits were filled with symmetrical, firm growths about the size of a small grapefruit. The eyelids, though capable of motion, could not close completely, as shown in the illustrations. The lower lids were infiltrated and firm;

3. Brown, R. K. L.: Renal Hydatid Disease, J. Urol. 23: 611-626 (June) 1930.

4. Dew, Harold: Some Complications of Hydatid Disease, Brit. J. Surg. 18: 275-293, (Oct.) 1930.

the veins were distended. The eyeballs were round, hard and white except where the lids did not cover them; there they were reddened. They were movable and not tender. In the pupillary areas were collections of yellowish red material.

Fig. 1.—Lateral view of patient.

The patient's nose was recessed between the bilateral growths. The hard palate was pushed down laterally, forming an inverted V, as the roof of the mouth.

There were no other abnormalities except for palpable enlargement of the cervical and epitrochlear lymph nodes, and

Fig. 2.—Front view of patient.

the following neurologic changes: The olfactory sense was impaired. The legs were spastic with hyperactive reflexes; there was ankle clonus, and the Babinski sign on the left foot was doubtful. The impression of the neurologist was that there was a moderate pressure on the pyramidal tracts and a growth, beginning either in the wall of the cavernous sinus on the left side or outside the sinus involving early cavernous

sinus drainage and making pressure on the optic chiasm or just in front of it on the optic nerves. If new growth was outside the sinus, he would suppose it was growing from the floor of the anterior fossa.

No calcification was revealed roentgenographically in the orbital tumors.

The following laboratory observations are recorded: The blood count and urinalysis were negative. The Wassermann reaction of the blood and spinal fluid was negative.

The treatment instituted was surgical removal of the growth, and the patient died.

The pathologic diagnosis was chronic inflammatory granuloma of the orbits, optic nerves, optic chiasm and lower part of the abdomen with hydronephrosis from the ureteral obstruction by granulomatous masses. The orbital growth was retrobulbar.

BACTERIAL ENDOCARDITIS INVOLVING THE RIGHT CHAMBERS OF THE HEART

ADOLPH SACHS, M.D., AND SVEN ISACSON, M.D., OMAHA

Subacute bacterial endocarditis is a moderately common occurrence in most larger clinics. Libman has presented this syndrome so clearly to the profession that the diagnosis in most cases is readily made. The Libman facies, the clubbing of the fingers, the chills, fever and sweats, the enlarged spleen,

Fig. 1.—Multiple septic infarcts in the lung.

the showers of infarcts, the petechiae, the positive blood culture, the history of an old valvular endocarditis, the moderately prolonged illness and the usual fatal ending are so characteristic

Fig. 2.—Bacterial endocarditis involving tricuspid valve.

that the profession is constantly alert to recognize its occurrence; but subacute or acute bacterial endocarditis involving only the right chambers of the heart is not common, and the profession at large should be awakened to this syndrome so that more cases will be recognized.

The right sided subacute bacterial endocarditis usually is found in old congenital heart lesions, but it may also occur without a recognizable congenital lesion. The symptoms of

right sided subacute bacterial endocarditis are the following: 1. Chills, fever, sweats, leukocytosis and the like are the same as in any septicemia. 2. Signs of atypical pulmonary infection are present with patchy areas of consolidation. These may be confirmed by x-ray examination. The consolidations are due to pulmonary infarctions. 3. The spleen may or may not be enlarged; if it is it is due to sepsis, not infarction. 4. A positive blood culture occurs late if present at all. 5. The history or physical signs of a congenital lesion are of value but may be absent. 6. Signs of a right sided heart lesion may or may not be present. 7. There is no clubbing of the fingers unless it is due to an old congenital lesion. 8. The diagnosis is often made by exclusion. 9. Peripheral emboli, except in the lungs, are absent.

The lesion should be suspected if the (1) chills, fever, sweats and leukocytosis are present; (2) there is protracted pulmonary infection due to multiple septic infarcts, as revealed by physical or x-ray examination; (3) there is a cardiac lesion involving the right chambers of the heart; (4) typhoid, paratyphoid fever, undulant fever, malaria and the like can be excluded.

REPORT OF CASE

We report an illustrative case with the autopsy. This case ran a moderately malignant course. The patient entered the hospital May 30, 1936, and died June 18.

Miss C. M., aged 52, had just recovered from double lobar pneumonia and on admission complained of pain in the right upper quadrant, chills and fever, and sweats.

The past history was practically negative except that radium had been used for menorrhagia six years before, with uneventful recovery. She had had no rheumatism or serious infectious diseases. She had been deaf since childhood.

May 1, 1936, while the patient was teaching at an institute for the deaf, she had a sudden severe pain in the right upper quadrant and fever. After examination it was found that she had a diaphragmatic pleurisy with double lobar pneumonia. She had a stormy illness but made a nice recovery, so that she was able to sit up and walk a little. May 30 she had a severe chill lasting about twenty minutes, nausea, vomiting, and a temperature of 104 F. She was taken to the hospital and complained of pain in the right upper quadrant. She had a hacking cough but no bloody or rusty sputum. On examination, signs of consolidation in the right upper and left lower lobes were present, and a diagnosis of delayed resolution was made. X-ray examination corroborated it. The chills and fever continued at irregular intervals and she remained tender over the right upper quadrant. The liver was so tender that at one time we were suspicious of a liver abscess. All the usual agglutinations for undulant fever, typhoid, paratyphoid fever and the like were negative. Lobular patches of consolidation were increasing, and we felt that this undoubtedly was associated with her chills and fever. No malarial parasites could be found.

We were constantly watching for an endocarditis because of other negative observations plus the large spleen, the chills and fever and sweats. The blood picture merely showed a marked secondary anemia and a leukocytosis. The patient had no petechiae, no clubbing of the fingers, no showers of infarcts and no hematuria. Since no murmurs were present we were loath to diagnose an endocarditis. A blood culture was positive for pneumococci, June 12.

Laboratory studies revealed: white blood cell count varied between 10,000 and 18,000, with 80 to 88 per cent polymorphonuclears and a marked secondary anemia.

Urine analysis was negative.

There was a soft systolic blow, which is often heard during high fevers, but it was not constant. No thrills or pericardial friction rubs were present.

The patient's condition improved somewhat and she had an unusual euphoria.

She felt bad only during the chills and fever, which lasted about twenty-four or forty-eight hours.

By exclusion we felt that the only diagnosis that could be made was that of a bacterial endocarditis of an unusual type. The patient died suddenly June 18 and a postmortem examination was permitted after the body was embalmed.

Autopsy revealed a right sided endocarditis with multiple septic emboli in the lungs. There were no infarcts elsewhere, which is characteristic of this type of right sided endocarditis.

External examination revealed a small, well nourished body. The skin and visible mucous membranes were very white and showed no special markings except for a superficial bruise on the right upper arm. The body had been embalmed and rigor was marked.

The body was opened in the midline. The thoracic organs appeared to be in normal positions. In the abdomen the spleen was prominent and extended four fingerbreadths below the left costal margin. The left lung was free, the lower lobe was consolidated and presented a round necrotic area 3 cm. in diameter on the anterior surface; on cut section there were seen many red infarcted areas varying in size and age. The right lung had many fine pleural adhesions. There was a small infarct in the lower lobe; the rest of the lung contained air throughout. Peribronchial and mediastinal lymph nodes were enlarged and anthracotic.

The heart was approximately normal in size and the posterior coronary vessels were tortuous. The tricuspid valves presented soft friable, firmly adherent thrombi on all three cusps. The largest was found on the posterior leaflet and measured 2 by 2 by 1 cm. The left chambers were empty and the mitral leaflets were clean. The root of the aorta showed small atheromatous areas. The aortic and pulmonic valves were clean.

Fig. 3.—Temperature.

In the abdomen the spleen was seen to be greatly enlarged, approximately three times normal size, with rounded edges and a "pink paint" friable pulp, characteristic of a septic spleen. The liver, gallbladder, pancreas and gastro-intestinal tract showed no gross abnormalities and no infarcts.

Both kidneys were large, lobulated and congested. The adrenals were normal in appearance. No infarcts were present except in the lungs.

The pelvic organs were small and the ovaries were sclerotic. In the lower uterine segment was seen a small subserous fibroid and at the fundus was seen a small mucous polyp.

Section of the lung taken through an infarcted area showed a solid mass of fibrin, red and white blood cells and a barely recognizable lung stroma. Surrounding alveoli were filled with an albuminous fluid.

A section of the thrombus on the tricuspid valve showed an amorphous mass of platelets and fibrin in the periphery of which were seen masses of lymphocytes, a moderate number of polymorphonuclears and pneumococci.

The anatomic pathologic diagnosis was: (1) acute ulcerative pneumococci endocarditis, (2) septic pulmonary infarcts, (3) serofibrinous pleurisy and (4) acute septic spleen.

COMMENT

It is apparent that the pneumonia became complicated by an ulcerative tricuspid valvulitis on which large soft vegetations quickly developed and in turn gave rise to septic emboli, with infarctions in the lung. Death resulted from acute cardiac failure.

PHYSICAL AND PHYSIOLOGIC PRINCIPLES OF AIR CONDITIONING

C. P. YAGLOU, M.S.

BOSTON

Air conditioning for comfort or health is the art of controlling the physical environmental factors to suit human requirements. Great strides have been made in the past few years along purely engineering lines, but our knowledge of human requirements is still incomplete and controversial.

In the present paper an attempt is made to digest and evaluate some of the basic physical and physiologic principles involved, and to point out where data are inadequate and where research is urgently needed.

THE NEED FOR AIR CONDITIONING

Alteration of the Atmosphere of Occupied Rooms.—

In rooms occupied by many persons the air is altered physically and chemically by the processes of body metabolism and decomposition of matter in the skin and clothing. Contrary to earlier workers, we are not at all concerned now with the changes of oxygen and carbon dioxide from respiratory processes, because they ordinarily are much too small to be of any physiologic significance. The leakage of air through cracks around windows and doors is usually sufficient to maintain the oxygen and carbon dioxide well within normal limits.

Changes in the electrical characteristics of air, though striking,¹ have not been proved to be significant to the comfort or health of individuals.²

Volatile Organic Matter.—More important than oxygen or carbon dioxide in occupied rooms is the ill defined odoriferous organic matter arising from foul breath, sweat and sebaceous secretions (especially when personal hygiene is deficient), gases from the alimentary canal, and decomposition of matter in the skin and clothing. Man's sense of smell is extremely sensitive to inconceivably small concentrations of odoriferous matter that cannot be detected by known methods of chemical analysis.

Such odors are not known to be harmful but they certainly induce a feeling of stuffiness and odor discomfort on entering a room from outdoors. Under extreme conditions headache, nausea, loss of appetite and a disinclination for physical activity³ may result in sensitive persons. Owing to olfactory adaptation, the occupants of a room may not be conscious of odor but they seem to be capable of detecting stuffiness or lack of freshness

in the air.⁴ The general agreement now is that all rooms should be provided with sufficient fresh air to prevent the accumulation of objectionable body odors.

The toxicity of expired air is constantly coming up in every discussion of the subject. Many persons, including a number of scientists, still hold the view that expired air may contain some poisons in minute concentrations; and, while a positive statement would be entirely unfounded, a negative view would be equally unwarranted. All one can say at present is that no poisonous substance has been demonstrated in expired air. Summaries of authentic contributions to both sides of this argument have been published by Billings, Mitchell and Bergey,⁵ Flügge,⁶ the New York State Commission on Ventilation,³ Frederick⁷ and Rosenau.⁸

Of considerable academic interest in this connection is a recent study by Gramenitzkii⁹ indicating a weakening action of expired air on the isolated frog heart that cannot be accounted for by the action of carbon dioxide. The air of old and sick persons was found to be more toxic than that of young and healthy individuals.

Microbic Dissemination in Rooms.—After a period of dormancy, the problem of air-borne infection has now come again to the forefront. Recent experiments by Colvin¹⁰ indicate that aerial infection beyond mouth spray limits takes place in occupied rooms. W. F. and M. W. Wells¹¹ have definitely shown that, although droplet infection is essentially localized and concentrated, infection by droplet nuclei is dispersed and dilute. Minute droplets, less than 0.1 mm. in diameter, ejected into the air by talking, sneezing and coughing, do not fall to the floor, as has been generally assumed,¹² but evaporate before they fall the height of a man. Pathogenic organisms in the dried droplet nuclei may remain suspended in the air for long periods and the virus may survive long enough to be transmitted to other persons in the same room or building.

By means of improved apparatus, Wells was able to recover droplet nuclei from cultures of resistant microorganisms a week after inoculation into an air-tight metal chamber. Organisms characteristic of the respiratory tract were recovered in small numbers forty-eight hours after inoculation, while organisms of the intestinal tract could not be recovered after eight hours. The Pfeiffer bacillus disappeared within an hour under the conditions of Wells's experiments.

The practical importance of these results in the transmission of disease depends on a number of complex factors, such as the specific character, virulence and number of infectious organisms encountered, the frequency of exposure, susceptibility of the individual, and so on, which need not be discussed here. According to

This is the first report of the committee established by the American Medical Association to study air conditioning. The committee includes: Carey P. McCord, Detroit, chairman; Emery R. Hayhurst, Columbus, Ohio; William F. Petersen, Chicago; Horatio B. Williams, New York, and Constantin P. Yaglou, Boston.

Dudley¹³ a certain minimum number of specific pathogenic organisms in the air is desirable and probably beneficial, as they stimulate immunity by acting as vaccines.

The probability of meeting pathogenic organisms in sufficient numbers to break down the natural body defense is intimately associated with the floor area and air space per person and the quantity of fresh air supplied. The problem is extremely complex, as it is difficult or impossible to separate contact infection from air-borne infection. Except in overcrowded and badly ventilated rooms, the danger is believed to be "much contracted in space, limited in time and restricted to comparatively few diseases."¹⁴ The value of ventilation in infection is stressed by many, particularly de Crespigny,¹⁵ Dudley,¹³ and Frederick.⁷

A recent development of considerable significance to contagious wards and operating rooms is the use of ultraviolet radiation for sterilizing air.¹⁶

Temperature, Humidity and Air Movement.—It is now generally recognized that the most important change in the air of occupied and poorly ventilated rooms is the increase of temperature and humidity caused by the heat and moisture given off from the skin and lungs of the occupants. The most common complaint in crowded rooms is not lack of ventilation but overheating; stuffiness and odors are secondary contributing causes. The depression and discomfort felt is similar to that experienced on a warm and humid summer day and the primary object of air conditioning, therefore, is to reduce the temperature and humidity to within comfortable limits. In cold weather this is done by the introduction of cool outdoor air after tempering it to a suitable temperature, with or without artificial humidification. In warm weather the air must be cooled and dehumidified.

A secondary object of air conditioning is to circulate a sufficient amount of fresh clean air through the room in order to dilute the odoriferous matter below the objectionable concentration. This must be accomplished without drafts. When these conditions are fulfilled, all other factors will be automatically taken care of satisfactorily under the usual conditions of life.

PHYSICAL AND PHYSIOLOGIC BASES OF COMFORT

Heat Regulation in Man.—Although life and heat are concomitant, the heat produced in the body is a by-product of metabolic processes and the amount is far in excess of the usual requirement for keeping the body warm. Nature has provided suitable means in the skin and lungs for the removal of the excess heat and for the maintenance of an optimum internal temperature.

A fundamental requirement of all living organisms is the ability to adapt constantly to the ever changing physical environment, which tends to upset the temperature equilibrium of the body. Under the usual conditions of life these adjustments are so easily accomplished that a normal person is unconscious of the complex physiologic processes at work. Discomfort arises when thermal equilibrium is impossible or when abnormal reactions are involved in the transitional period of adaptation. The ability to adapt varies widely; metabolism, peripheral circulation and physical

and subjective symptoms show great variability in different persons under identical environmental conditions.

Sensations of heat or cold are not due to changes in internal body temperature but largely to changes in the temperature of the skin. Although every physiologist accepts the existence in the brain of a heat regulating center that coordinates the multitude of functions involved in heat regulation, there is considerable controversy as to how this heat center is normally stimulated.

According to the prevailing school of thought, induction of the stimulus is by afferent neurons with endings in the skin that are sensitive to temperature. The actual existence of such receptors has never been demonstrated, although the experiments of Adrian,¹⁷ Bazett,¹⁸ Dallenbach¹⁹ and Strughold and Karbe²⁰ are particularly suggestive.

An alternate view is that only a small change in the blood temperature is sufficient to stimulate the central nervous system. The evidence on both sides is admirably reviewed by Martin²¹ and Ranson²² and it would seem that both theories may be true. That the heat regulating center is itself sensitive to temperature was demonstrated by Barbour,²³ Moorhouse²⁴ and others.

By whatever means the centers may be aroused, efferent neurons transmit the activating impulses from the central nervous system to the various organs of the body controlling heat production and heat loss for the restoration of normal body temperature. The organs involved in heat production include the musculature, the liver and the endocrine glands; those primarily concerned with heat loss are the blood vessels of the skin and lungs and the sweat glands.

Under ordinary conditions, the vasomotor changes are apparently induced by nerve reflexes. The cutaneous blood vessels are also affected through the sympathetic nerves by the action of cold on distant parts of the body's surface. According to Martin,²¹ direct sensitivity of the centers to the temperature of the blood returning from the skin is essential for the control of the reflex mechanism after the latter has accomplished its purpose. Otherwise the reflex action would become progressive and the internal temperature would continue to rise or fall with a fall or rise in the skin temperature.

The workings of the heat regulating mechanism are extremely complex and are not well understood. When the external temperature rises, the blood vessels of the skin dilate by reflex vasomotor action and probably by the direct action of heat on the vessels. More blood flows through the skin, thus raising its temperature and therefore the heat loss. The rise is least in the skin of the forehead and trunk and greatest in the extremities, particularly the feet.²⁵ If this method of

cooling is not sufficient to prevent a rise of body temperature, the sweat glands are thrown into full action by the stimulus of the heated blood flowing through the center. Finally the activity of the adrenals and the thyroid is depressed by sympathetic inhibition and the metabolism is lowered.²⁶ In this way thermal equilibrium may be reestablished if the external temperature is not too high.

On exposure to cold, a reverse action takes place. The skin vessels constrict and the blood supply is curtailed in order to conserve body heat. If this response fails to prevent the body temperature from falling, there is a definite increase in metabolism, effected partly by voluntary muscular contractions and partly by stimulation of the adrenals and thyroid.²⁷ Such alterations in endocrine secretion are probably the chief factors involved in the adaptation of the organism to warm and cold climates.

Comfort as Related to Physical Air Factors.—Comfortable air conditions are those under which the human body is able to maintain a normal balance between the production and loss of heat at normal body temperature

Chart 1.—Heat production and heat loss of healthy young men in relation to "effective temperature." Curve A, courtesy Archives of Internal Medicine.²⁷ Curves B and C, men seated at rest; after Houghten, Teague, Miller and Yant,²⁸ courtesy American Journal of Physiology.

without the individual being conscious of undue effort on the part of the heat regulating mechanism. Heat loss should preferably take place in the manner to which the individual has been adapted by climate, season, clothing and general living conditions. This is not generally recognized, however; the prevailing belief is that the method of heat loss makes little difference to the comfort of an individual as long as the total heat loss is adequate. If this were true, one should be comfortable when the entire heat loss takes place by evaporation of sweat with total metabolism and heat loss remaining normal, as for instance on exposure to a temperature of 100 F. and a relative humidity of 20 per cent (chart 1).

Four principal factors are generally recognized as affecting comfort and quality of the air: temperature, radiation, air movement and humidity. None of these are independent of the others, and the human body

reacts to them as a whole. Wide national and international differences of opinion exist concerning the application of these factors.

No comfort standards can be fixed to apply under all conditions, although it is possible to derive limits that would meet the requirements of a majority in any given homogeneous group under certain conditions. The factors determining the selection are largely individual, owing to wide biologic diversity and variable response of different persons to a given physical environment. Climate and season, social and economic status, state of health, age, sex, clothing, activity and degree of native or acquired adaptation are among the important modifying factors. The variation in temperature may be from 50 to 100 F., with a very wide range of humidity.

Still more difficult to fix are the optimum air conditions for health, since an individual's health is a complex physiologic balance, an "imponderable subjective and objective" that cannot be expressed in terms of physical units. We must therefore content ourselves with evaluating health aspects of air conditions on the basis of physical comfort or discomfort, records of colds, physical and mental efficiency and the like, however variable and relative these criteria may be.

Under ordinary conditions the total metabolism and heat loss remain substantially constant over a rather wide range of temperature and humidity (chart 1), but the degree of comfort experienced may vary considerably within this range, depending on the adjustments the body must make to maintain heat equilibrium. Owing to a number of physical, physiologic and psychologic factors, thermal equilibrium is never entirely fulfilled at any given moment, as shown by fluctuations of body temperature and metabolic rate within certain limits even under basal conditions. Over a period of time, however, the assumption of thermal equilibrium must necessarily hold true.

Heat loss from the human body takes place by radiation to surrounding walls and objects, by conduction and convection to surrounding air, and by evaporation of moisture from the lungs and skin. Under comfortable conditions during the heating season, radiation usually accounts for between 46 and 60 per cent of the total heat loss, convection for from 15 to 30 per cent, and evaporation for from 20 to 30 per cent. The variation in loss through these different channels depends largely on physical and physiologic factors, the former including the temperature of the air and walls and the body surface exposed. The physiologic factors include the state of health, metabolic rate, vasomotor control and other secondary factors. At the usual indoor temperature of 70, the average normal radiation loss is approximately 50 per cent of the total loss, convection loss is 25 per cent, and evaporation loss is 25 per cent.²⁹

Loss of heat by radiation depends on the temperature of the surrounding walls and objects and is independent of air temperature. The rate of loss is according to Stefan's fourth power law as demonstrated by Aldrich,²⁹ Fishenden and Saunders²⁸ and recently by Winslow and his co-workers.³⁰ Air temperature directly affects heat loss by convection from the surfaces of the body and indirectly by evaporation, as will appear later. Air

movement increases convection loss and reduces to some extent the radiation loss by lowering the surface temperature of the body. With powerful air currents, convection loss may become a very important factor, but such conditions are outside the limits of comfort.

About 9 per cent of the total heat loss takes place by evaporation from the lungs and upper respiratory passages, and 16 per cent by evaporation from the skin. To an insignificant extent the former varies with vapor pressure of the water vapor in the air and is therefore a function of absolute humidity to that small extent. Evaporation from the skin is limited to the amount of moisture present on it, and this amount remains substantially unaffected by humidity and, up to a certain point, by temperature also,³¹ as shown in chart 2. Insensible perspiration is now known to be largely diffusion of water through the capillaries and is almost independent of sweat gland activity.³² Sweating is an emergency process that comes into play in warm environments or during muscular work, and the output of sweat is controlled not by humidity but by temperature (chart 2). Von Willebrand,³³ Adolph,³⁴ Houghten,²⁸ Campbell and Angus³¹ and many others have shown that insensible perspiration increases gradually with the environmental temperature up to a certain critical temperature of about 90 F., at which point visible sweating breaks out. The importance of humidity on sensation of warmth and comfort follows the temperature and perspiration curve; it is minimum during the heating season, as Howell,³⁵ Miura,³⁶ Phelps and Voit,³⁷ the New York State Commission on Ventilation³ and the effective temperature index³⁸ indicate, and maximum during warm weather when profuse sweating takes place. Heat loss by radiation and convection follows an opposite course, decreasing with increasing temperature, as shown in chart 2.

The important factors in air conditioning during the heating season are, therefore, the temperature of the air and of the enclosure and the rate of air movement with respect to drafts. In buildings of good construction, heated by the usual convection methods, the temperature of exposed walls is but a few degrees below air temperature, and the air movement is usually between 15 and 50 feet per minute. Consequently, air temperature is the predominant factor. In most localities in the United States, where central heating is used for from six to eight months of the year, a temperature between 69 and 73 F. with natural or moderately low humidity and freedom from drafts will meet the requirements of the majority of persons of sedentary pursuits. Lower temperatures are indicated in manual labor, depending on the degree of exertion.

Humidity.—The human body has no receptors in the skin for recognizing degrees of humidity, but it is

affected indirectly in a physical manner when the temperature is either too low or too high. At temperatures below 45, a high humidity makes the air feel colder because it increases the heat conductivity of clothing. At high temperatures a high humidity makes the air feel even warmer, because it interferes with evaporation of perspiration.

Under ordinary indoor conditions during the heating season, variations of humidity are relatively unimportant as far as warmth and comfort are concerned, and from the standpoint of health there are no data to prove that artificial humidification is necessary. With the exception of Huntington's³⁹ statistical studies and the clinical studies of Blackfan and Yaglou⁴⁰ on premature infants, practically all physical, physiologic and psychologic tests have proved to be negative or inconclusive.⁴¹ No one disputes the injurious effect of low humidities to household furniture, but the argument about health has little foundation in proved fact.

Extremely low humidities of the order of 15 per cent or less may affect our comfort and possibly our health by drying the mucous membrane of the nose, but such

Chart 2.—Normal heat loss by evaporation and by radiation and convection combined, in relation to environmental temperature and humidity. After Houghten, Teague Miller and Yant,²⁸ courtesy American Journal of Physiology.

humidities are unusual unless the air is overheated. During the coldest months of the year the ordinary variation is between 20 and 30 per cent. The walls and furnishings of a room, although apparently dry, are capable of storing large quantities of moisture when the humidity is relatively high⁴² and releasing it when the humidity falls. For this reason the relative humidity never falls to the theoretical minimum of about 5 per cent in zero weather—a value often used as an argument in favor of artificial humidification.

Although normal persons generally prefer a low humidity (25 per cent) to a high one (40-60 per cent) when given an opportunity to compare the two in adjoining conditioned rooms, sufferers from frontal sinusitis and other infections of the upper respiratory tract characterized by excessive dryness of the nose have shown a strong preference for the high humidity.

ties.⁴³ According to them, humid air was fresher and easier to breathe than air of the same temperature but of lower moisture content. The same subjects, however, disliked the humid air after their condition cleared up. In catarrhal conditions of the nose a low humidity also seems to be more agreeable than a high one,⁴⁴ but data on this are too limited at present to serve as a basis for final conclusions.

The tendency to dryness of the nose and throat under low humidities and its possible effect on respiratory disorders should be investigated. Possible disturbances of water balance and symptoms of discomfort under extremes of humidity should also be investigated with the temperature kept at normal.

Air Movement and "Freshness."—Air freshness as perceived by the normal nose is mainly a function of temperature, humidity and amount of odoriferous matter in the air. Moderately dry and cool air is fresh and invigorating, whereas warm air is stuffy and depressing, no matter how pure it is chemically.

Body odors, odors from scorched dust settling on radiators and odors from gaseous products of combustion in industrial districts detract considerably from the freshness and pleasantness of air.⁴⁵

Hill⁴⁶ attributes the chief cause of stuffiness in a heated room to the long infra-red rays emitted by dark or dull red sources of heat. He ascribes the congestion in the nose not to a direct effect of heat on the mucous membrane, as is generally believed, but to specific electromagnetic wavelengths acting reflexly from the sensory nerves of the skin. Rays from bright luminous sources ("nose-opening" rays) have an opposite effect, according to Hill, but this could not be demonstrated by others.⁴⁷

Air freshness as perceived by the skin is a function of temperature, air movement variability and humidity. The agreeable sensation of freshness is ascribed to a stimulating action of the cutaneous sensory nerves by mild air currents within the threshold of perceptibility. According to Baetzer⁴⁸ the threshold current on the skin of the cheek has a velocity of from 40 to 60 feet per minute at normal room temperatures. On the skin of the feet the threshold values seem to be considerably lower. The greater the temperature, the greater the threshold velocity and vice versa. A uniform air movement is regarded as monotonous and less stimulating than oscillating air currents below and above the threshold velocity. Here may lie, in part, the explanation for the preference of window ventilation over the mechanical systems, with temperature fluctuations closely related.

Temperature Changes.—Although a moderate variability of temperature is generally considered to be stimulating and probably beneficial, there is a happy medium beyond which extremes are destructive. Great contrasts such as those experienced in passing from an overheated room to cold outside air appear to be harmful to the mucous membranes of the upper respiratory

passages. The deleterious effects of low or high temperatures, apart from acute conditions (frost bite, heat stroke) do not seem to be due to cold or heat per se but largely to great temperature contrasts which produce congestion and ischemia and weaken the physiologic defenses against bacterial proliferation. Respiratory diseases and rheumatism are the chief disorders associated with exposure to great temperature changes. The highest rates are seen among iron and steel workers, miners, outdoor laborers and others who habitually expose themselves to great temperature contrasts.⁴⁹

The condition of the vasomotor system may play an important rôle in the whole situation for, as is well known, a secondary reactive vasodilatation occurs in healthy individuals during exposure to cold, with a rise of skin and deep tissue temperature and a general feeling of warmth. Metabolism and heart action are increased and the organism is in a better position to withstand the cold.

An adequate vascular system may not be successful in overcoming the ischemia incident on chilling. The vessels of the skin and nasal membranes remain constricted and the blood is diverted to the internal organs. Metabolism does not increase sufficiently to prevent the body temperature from falling. There is much good evidence to show that difficulties with the heat regulating mechanism of the body are fundamental in the predisposition to colds and other more serious ailments.

The inability of Kerr and Lagen⁵⁰ to transmit common colds from carriers to susceptibles in an air conditioned chamber might be explained by the control of predisposing environmental factors. Their experience, as well as that of Van Loghem⁵¹ and others, does not necessarily contradict the widespread belief in the contagiousness of the common cold even though the specific organism causing it has not as yet been identified.

Petersen⁵² and Mills⁵³ lay great stress on the effects of frequent atmospheric changes of temperature and barometric pressure which lead to nervous instability and a number of diseases of exhaustion.

Drafts.—In dealing with drafts, much simplification is possible by defining the conditions productive of drafts at the feet, the part of the body most sensitive to drafts owing probably to the comparatively poor blood circulation there. The back, the back of the neck and the top of the head are also sensitive to drafts, but the draft threshold of these parts is higher than that of the skin of the feet.

Although drafts and cold feet are often due to faulty heating and air distribution systems, the complaints under ordinary room conditions, coming as they do usually from a comparatively small percentage of the occupants, would seem to be more often associated with poor blood circulation and deficient vasomotor response than with faulty air conditions. They are apparently the result of a tendency to instability of the heat regulating mechanism in certain individuals as well as in normal persons under certain circumstances.

Numerous observations on myself at various times of the year for three consecutive years have shown an enormous variability of foot temperature and sensitivity to drafts under approximately identical conditions in my office while working at a desk for at least two hours before making observations. With comfortable breathing zone temperatures between 70 and 74 F., floor temperatures of 67 to 74, and air movement about the feet of from 20 to 70 feet per minute, the temperature of my feet near the ankles varied from 75 to 91 F. during the months of December to March. Much higher skin temperatures were recorded on all other parts of the body, the temperature ranging from 90 to 98 F. While the average foot temperature showed some relationship to floor temperature and air movement, many individual observations of different days showed no consistent relationship at all.⁴³ Bedford²⁵ likewise observed a great variability of foot temperature among a large group of British factory workers performing light work.

My threshold of draft occurred at a foot temperature of 80-82 F., regardless of air conditions. Uncomfortable drafts were felt at foot temperatures under 80. The lowest foot temperatures and the greatest difficulty with drafts were experienced during the month of February 1936, when I had a bad cold of long duration accompanied by considerable loss of weight. The highest foot temperatures (94-97 F.) were observed during the warm months of the year when the room temperature was between 85 and 95.

Complaints of drafts or cold feet from among large groups of men, women and children in experimental conditioned rooms occurred at any floor level temperature equal to or lower than the comfortable breathing zone temperature and at all air velocities produced by the apparatus; namely, from 20 to 65 feet per minute. The majority of the complaints came from women. The lowest foot temperature observed in this group was 74 and the highest 93, both under ordinary room conditions during the heating season. The lowest draft threshold occurred at a foot temperature of 78.

Theoretically it may be possible to reduce complaints of drafts among the minority by raising the foot level temperature and reducing the air movement to below the threshold of perceptibility. Practically this is difficult to accomplish with conventional heating systems without overheating the breathing zone for the majority of occupants. The problem would seem, therefore, to be one for the individual himself to solve by the use of suitable clothing that will protect the extremities against too rapid heat loss and in this way to compensate for inadequate vasomotor response. In order to assist the vasomotor system, certain reasonable limits of foot level temperature and air movement must be established that will be agreeable to the majority of normal individuals. Observations by Houghten⁵⁴ and those of my own indicate a foot level temperature not more than 2 degrees F. below the comfortable breathing zone temperature, with an air movement not over 40 feet per minute during the heating season.

Drafts on the feet or any other part of the body have a tendency to induce reflex vasoconstriction in the entire superficial area and vasodilatation in the mucous membranes of the nose. The blood pressure may rise and nasal capillary hemorrhage may result in sensitive persons. The problem has a great bearing on comfort

and health and deserves far more attention and study than it has hitherto been given.

Atmospheric Pollution.—Aside from specific industrial conditions, dusts, smoke and gases of combustion in ordinary city air are generally believed to be not so much matters of health as of nuisance and esthetics, capable of affecting comfort directly or indirectly. Although the damage to property and vegetation is considerable and generally recognized, the evidence on health aspects is quite controversial except under extreme conditions of pollution.⁵⁵

The control of atmospheric pollution is primarily a problem of city planning, but under present circumstances it has been more expedient to deal with it inside the buildings as part of air conditioning. Activities within the building itself constitute another source of pollution. The use of tightly fitting storm sashes and doors in conjunction with vacuum cleaning helps a great deal in reducing dustiness. The advantages of air filtration are limited to the larger dust particles, as very fine dusts, smoke and gases defy most of the filters in common use.

55 Shattuck Street.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT. HOWARD A. CARTER, Secretary.

SPERTI SUNLAMP NOT ACCEPTABLE

Manufacturer: Science Laboratories, Inc., 424 East Fourth Street, Cincinnati (Successor to Science Laboratories).

One of the functions of the Council on Physical Therapy is to report, from time to time, on newly marketed devices recommended for use in physical therapy.

Such a device is the Sperti Sunlamp, regarding the merits of which the Council has recently received inquiries.

I. CONSTRUCTION AND OPERATION OF THE SPERTI SUNLAMP

This device consists of two lamps—the one within the glass enclosure of the other—constructed somewhat as described in U. S. patents 1,956,958 and 1,976,149. The outer bulb contains an incandescent tungsten filament, which provides a source of visible radiation. The much smaller, inner tubular enclosure contains a globule of mercury and electrically heated electrodes, which produce a thermionic conduction through the mercury vapor. The tubular enclosure of the mercury arc lamp is made of thick glass to absorb the rays of wavelengths shorter than about 2,800 angstroms.

The combined lamp can be screwed into an ordinary lighting fixture, without additional starting or controlling devices, and used in place of the ordinary incandescent lamp of similar wattage.

The lamps examined are designed for use on 110 to 120 volts and consume about 100 watts on about 115 volts. A considerable portion of the electric power consumed is used in the inner, mercury vapor, lamp. The temperature, candle power and ultraviolet emission of the tungsten filament in the Sperti Sunlamp is therefore considerably lower than that of a commercial 100 watt tungsten filament lamp, on normal operation.

For example, the illumination at one foot below the Sperti Sunlamp (in a frosted bulb, aluminum reflector, type NR) was 70 foot candles as compared with 120 foot candles for a

Med.* 7:751 (Sept.) 1931. Ruskin, S. L.: Pollution of the City Air as a Source of Nose and Throat Disturbance, *Science* 84:84 (July 24) 1936. Ventilation and Atmospheric Pollution, *Rept. Comm. on Ventilation and Atmospheric Pollution*, *Am. Pub. Health A. Year Book*, 1934-1935.

regular commercial 100 watt tungsten filament lamp (frosted bulb, no reflector). This information is of importance if an attempt is made to use the lamp for illumination.

II. ADVERTISING MATTER

No advertising matter was submitted by the firm. The advertising literature, sent to the Council by the public, contained unsubstantiated statements. The advertising in the daily newspapers, by purveyors of these lamps, if intelligently interpreted, gives ample warning to the prospective purchaser that the ultraviolet intensity of the Sperti Sunlamp is low and that he need not expect to obtain much ultraviolet from such a lamp, unless he has the patience to spend enough time under it to get a sufficient dose.

III. PHYSICAL MEASUREMENTS OF SPERTI SUNLAMPS

In the course of a year, five samples (three shipments) of Sperti Sunlamps were investigated in a laboratory acceptable to the Council. Three of the lamps were in frosted bulbs with aluminum reflectors attached (type NR 110 to 120 volts) and two of the lamps were in bulbs of clear glass—the one having a neckband reflector of aluminum. All lamps were new and in good condition. By means of a voltmeter and ammeter the power consumed in the lamp was regulated to 100 watts (about 115 volts) as specified.

1. *Spectral Radiation Measurements.*—Owing to the reduced temperature, the ultraviolet spectral intensities of the tungsten filament are too low for measurement. Using a Sperti Sunlamp in a bulb of clear glass, spectral intensity measurements were made on the emission lines of the mercury arc at 2,967, 3,024 and 3,132 angstroms and longer wavelengths. The relative spectral intensities of the mercury arc were found much the same as observed in certain types of acceptable sunlamps enclosed in glass bulbs. The total intensities, however, are much lower, owing to the small size of the arc.

2. *Integrated Ultraviolet and Candle Power Measurements.*—The illumination (foot candle) measurements were made with a newly standardized General Electric illuminometer. The integrated ultraviolet intensities were measured with a dosage intensity meter, consisting of a balanced amplifier, photo-electric cell and micro-ammeter. The titanium photo-electric cell used has its maximum spectral photo-electric response at 2,950 angstroms and it is insensitive to wavelengths longer than about 3,300 angstroms. It therefore gives a physical measurement of biologically effective radiation. By means of a filter, the measurements are confined principally to wavelengths 3,132 angstroms and shorter, recognized as having a specific effect in curing rickets. In the case of the Sperti Sunlamp this biologically effective radiation is confined principally to the three emission lines of the mercury arc at 2,967, 3,024 and 3,132 angstroms, respectively, the ultraviolet radiation contributed by the tungsten filament being exceedingly small. These three emission lines of the mercury arc therefore act as a substitute for the band of ultraviolet of wavelengths 2,950 to 3,132 angstroms in sunlight.

At a distance of one foot below the lower edge of the type NR frosted bulb lamps, the illuminometer indicated an intensity of 70 foot candles (100 watts in the lamp), and the intensity of the ultraviolet of 3,132 angstroms and shorter wavelengths was 0.07 micro-ampere (μA) on the ultraviolet meter (average of two lamps). In contrast, by actual measurement, 70 foot candles of sky light (noon day and mid-winter) through an open window produced a micro-ammeter reading of 0.35 micro-ampere per foot candle; the ultraviolet in sky light is five times that of the Sperti Sunlamp. Accepting the manufacturers' statement that the biologically active ultraviolet, per foot candle of the visible energy, is a close approximation of natural sunlight, with only 70 foot candles available in the Sperti Sunlamp as compared with from 8,000 to 10,000 foot candles in noon hour, midsummer sunlight, the total ultraviolet intensity in sunlight is from 100 to 150 times that available in the Sperti Sunlamp.

By calibrating the photo-electric ultraviolet meter against a standard of ultraviolet radiation, the intensity of the ultraviolet of wavelengths shorter than and including 3,132 angstroms at one foot below the Sperti Sunlamp (on 100 watts) was found to be 0.392 $\mu W/cm^2$ or 0.098 $\mu W/cm^2$ at two feet—the standard distance.

The Council's specification for acceptance of this type of sunlamp, for home use, is 27 $\mu W/cm^2$. In other words, the ultraviolet intensity of the Sperti Sunlamp (at two feet distance) is only about $\frac{1}{275}$ the value required for acceptance by the Council.

When the company was first informed that the Council voted not to include the Sperti Sunlamp in its list of accepted devices, the firm replied that it wished to submit biologic evidence; hence, publication of the Council's previously prepared report was postponed.

The evidence presented consisted in part of protocols of experiments on the prevention of rickets in rats by means of irradiation with Sperti Sunlamps. Test rats, fed a vitamin D free diet (Steenbock 110), were exposed to a battery of five Sperti Sunlamps at a distance of 15 inches for a minimum of two hours daily for twenty-one days. A similar group of rats was exposed to irradiation from five 60 watt tungsten lamps for two hours daily; a third group was fed the basal vitamin D free diet supplemented with adequate amounts of vitamin D, and a fourth group was retained as a negative control. In each instance the five lamps were fixed in a reflector of size $8\frac{1}{2}$ by 20 by 34 inches, made of sheet iron lined with aluminum foil. The average percentage of bone ash in each group of rats is reported as follows:

	Per Cent
Positive control	46.72
Sperti Sunlamp	47.00
Incandescent lamp	35.43
Negative control	34.51

Data were also submitted regarding the prevention of rickets in chickens fed an unspecified rachitogenic diet. The chickens were divided into three groups; one group was exposed to indirect light; the second group was housed under identical conditions, but the indirect light supplemented by irradiation from an unspecified number of Sperti Sunlamps for eight hours daily; the third group was housed under the same conditions, but the indirect light was supplemented by irradiation from an unspecified number of Sperti Sunlamps for four hours daily. In each instance the experiment was continued over a period of four weeks. The distance from the lamp to the chickens was not given. Roentgenograms of the leg joint of the chickens were submitted. These roentgenograms indicated that the chickens irradiated by the Sperti Sunlamps were protected from rickets. Photographs of two of the irradiated chicks showed them improved in health but still rough feathered.

The firm's report was given careful consideration. It was noted, however, that prolonged irradiation from a number of the lamps was required to produce an antirachitic effect in either rats or chickens. In the case of rats it was necessary to place the reflector containing five Sperti Sunlamps at a distance of 15 inches from the backs of the animals.

The foregoing biologic evidence, in the opinion of the Council, was not satisfactory and the firm was given an opportunity to submit further biologic data.

These consisted of irradiation tests on rats, housed in screened cages, 20 by 18 by 18 inches, and fed on a rickets-producing diet. The lamps used to irradiate the rats were of the clear glass bulb type, mounted horizontally in the tops of the cages so that the mercury vapor arcs were approximately in the center of the cages. An aluminum painted reflector was mounted directly above each light. It appears therefore that the heads (ears) and backs of the rats were at a distance of 5 to 7 inches from the mercury glow discharge in the lamp.

The rats, thus housed, were irradiated two hours daily and, at the expiration of seven days, roentgenograms of the leg joints showed appreciable healing of rickets.

This supplementary report was given careful consideration. It was noted that the lamp had not been operated in a practicable position; that if the lamp had been operated in the customary manner (lamp vertical) and at the customary distance of 24 inches, the intensity would have been reduced by one fourth to one seventh, requiring an exposure of eight to fourteen hours or more daily, as compared with the two hours daily used to effect the healing indicated in the roentgenograms. It was noted also that the results obtained with the one lamp at the shorter distance supported the evidence of healing of rickets obtained with five lamps at approximately twice the distance, rejected in the preceding consideration of this lamp.

In the meantime the Council in cooperation with its consultants and referees gave careful consideration to the specifications for acceptance of sunlamps. They agreed that the present specifications of intensities for acceptance of ultraviolet lamps for use by physicians and sunlamps sold for use by the laity, are fair and reasonable and require no revision.

In the opinion of the Council, the biologic data submitted indicate that the antirachitic potency of the radiation from the Sperti Sunlamp is very low; as already noted in the physical measurements. The ultraviolet intensity of this lamp does not meet the specifications of the Council for acceptable ultraviolet lamps for home use. Therefore the practicability of the use of the Sperti Sunlamp for the prevention of rickets in children based on these data is not convincing. The Council therefore reaffirmed its previous stand and voted not to include the Sperti Sunlamp in its list of accepted devices.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary.

ACETARSONE-ABBOTT (See New and Nonofficial Remedies, 1936, p. 90).

The following dosage forms have been accepted:

Tablets Acetarsone, 0.05 Gm.
Tablets Acetarsone, 0.1 Gm.

TETANUS TOXOID, ALUM PRECIPITATED (See THE JOURNAL, May 16, 1936, p. 1735; Revised Supplement to New and Nonofficial Remedies, 1936, p. 16).

Eli Lilly and Company, Indianapolis, Ind.

Tetanus Toxoid, Alum Precipitated (Lilly).—Marketed in packages of two 0.5 cc. vials (one immunization treatment); and in packages of one 5 cc. vial (five immunization treatments).

CALCIUM GLUCONATE-ABBOTT (See THE JOURNAL, March 20, 1937, p. 973).

The following dosage form has been accepted:

Tablets Calcium Gluconate-Abbott (Flavored), 1 Gm. (15½ grains).

SALYRGAN (See New and Nonofficial Remedies, 1936, p. 308).

The following dosage form has been accepted:

Suppositories Salyrgan: Each suppository contains salyrgan 0.4 Gm., corn starch 0.1 Gm., and cocoa butter 1.3 Gm.

DEXTROSE (See New and Nonofficial Remedies, 1936, p. 290).

The following dosage forms have been accepted:

The Sterisol Ampoule Corporation, Long Island City, N. Y.

Sterisol Ampoule Dextrose 2½% in Physiological Solution of Sodium Chloride: A solution containing in each 100 cc. 2.5 Gm. of anhydrous dextrose and 0.85 Gm. of sodium chloride. Supplied in ampules containing 250, 500 and 1,000 cc.

Sterisol Ampoule Dextrose 10% in Physiological Solution of Sodium Chloride: A solution containing in each 100 cc. 10 Gm. of anhydrous dextrose and 0.85 Gm. of sodium chloride. Supplied in ampules containing 250, 500 and 1,000 cc.

Sterisol Ampoule Dextrose 20% in Physiological Solution of Sodium Chloride: A solution containing in each 100 cc. 20 Gm. of anhydrous dextrose and 0.85 Gm. of sodium chloride. Supplied in ampules containing 250, 500 and 1,000 cc.

Sterisol Ampoule Dextrose 25% in Physiological Solution of Sodium Chloride: A solution containing in each 100 cc. 25 Gm. of anhydrous dextrose and 0.85 Gm. of sodium chloride. Supplied in ampules containing 250, 500 and 1,000 cc.

Sterisol Ampoule Dextrose 5% in Distilled Water: A solution containing in each 100 cc. 5 Gm. of anhydrous dextrose. Supplied in ampules containing 250, 500 and 1,000 cc.

Sterisol Ampoule Dextrose 10% in Distilled Water: A solution containing in each 100 cc. 10 Gm. of anhydrous dextrose. Supplied in ampules containing 250, 500 and 1,000 cc.

Sterisol Ampoule Dextrose 20% in Distilled Water: A solution containing in each 100 cc. 20 Gm. of anhydrous dextrose. Supplied in ampules containing 250, 500 and 1,000 cc.

Sterisol Ampoule Dextrose 25% in Distilled Water: A solution containing in each 100 cc. 25 Gm. of anhydrous dextrose. Supplied in ampules containing 250, 500 and 1,000 cc.

Council on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COUNCIL ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION AND WILL BE LISTED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED.

FRANKLIN C. BING, Secretary.

HERSHEY'S BRAND CHOCLATIER

Manufacturer.—Hershey Chocolate Corporation, Hershey, Pa.

Description.—Powdered mixture of chocolate liquor, roasted cacao beans, powdered skim milk and pulverized cane sugar.

Manufacture.—Skim milk powder, chocolate liquor and pulverized cane sugar are mixed, cooled, sieved and automatically packed in glassine envelopes, which are mechanically sealed and packed in boxes.

Analysis (submitted by manufacturer).—Moisture 1.1%, ash 2.9%, ash insoluble in water 1.9%, ash insoluble in acid 0.02%, fat 16.0%, cacao fat 15.9%, milk fat 0.1%, protein (noncaffeine and nontheobromine $N \times 6.25$) 13.6%, sucrose 42.8%, lactose 14.4%, skim milk solids 27.4%, crude fiber 0.8%, carbohydrates other than crude fiber (by difference) 65.6%, *theobromine 0.4%, *caffeine 0.03%.

Moisture-free, fat-free and sugar-free, milk solids free basis—ash 6.3%, ash insoluble in acid 0.2%, crude fiber 6.2%.

Calories.—4.60 per gram; 131 per ounce; 196.5 per envelop (1½ ounces).

* By Prochnow's Modification of the Beckurts-Fromme method, *Arch. d. Pharmaz.* 247: 698, 1910.

SEXTON BRAND GRAPEFRUIT, WATER PACKED

Manufacturer.—John Sexton & Company, Chicago.

Description.—Canned grapefruit, packed in water.

Manufacture.—Grapefruits are steam heated, hand peeled, subjected to alkali bath, water sprayed and dipped in cold water. Sections are removed by hand, seeded and placed in cans to which water has been added. Cans are exhausted, sealed and processed.

Analysis (submitted by manufacturer).—(Analysis of entire contents including liquid): moisture 91.4%, total solids 8.6%, ash 0.34%, fat (ether extract) 0.2%, protein ($N \times 6.25$) 0.6%, crude fiber 0.14%, carbohydrates other than crude fiber (by difference) 7.4%.

Calories.—0.33 per gram; 9 per ounce.

Claims of Manufacturer.—For diets in which sweetened fruit is proscribed.

LOUELLA BUTTER

Distributor.—American Stores Company, Philadelphia.

Description.—Packaged, salted, pasteurized butter scoring 92 points or over by U. S. Department of Agriculture standards.

Manufacture.—Cream produced by tuberculin tested cows is delivered four times weekly and inspected for cleanliness, flavor, odor and acidity. The cream is pasteurized, cooled, strained and churned. The butter is washed with cool water, salted, tested for moisture, printed into blocks, cooled, wrapped and packed.

Analysis (submitted by manufacturer).—Moisture 15.9%, total solids 84.1%, milk fat 80.7%, curd 0.7%, sodium chloride (NaCl) 2.6%.

Calories.—7.26 per gram; 206 per ounce.

STANDBY BRAND TOMATO JUICE

Distributor.—Fine Foods, Inc., Seattle and Minneapolis.

Packer.—Vincennes Packing Corporation, Vincennes, Ind.

Description.—Pasteurized tomato juice with added salt; retains in high degree the vitamin content of the raw juice; the same as Alice of Old Vincennes Tomato Juice (*THE JOURNAL*, Feb. 20, 1932, p. 640).

SATURDAY, MAY 15, 1937

CANCER OF THE LUNG

Cancer of the lung seems unmistakably to be steadily increasing in frequency. This increase, both relative and absolute, cannot be explained as being solely due to improvement in diagnostic technic and to more careful postmortem studies. Accurate descriptions may be found in the writings of Rokitsansky, Virchow, Laënnec, Graves and many others. Whereas older clinicians regarded it as rare, it has in the past two decades come to occupy a place second in importance only to such common localizations of malignant growths as the stomach, the uterus and the rectum. This fact has been emphasized in England, in the United States and to an even greater degree in central Europe. The incidence, as cited in recent statistical reports, varies between 5 and 10 per cent of all cancers.

Among the contributing factors to this increase, the injurious effects of tobacco smoking, exhaust gases from automobiles, tar on roads and the influenza epidemic of 1918-1919 have been suggested. None of these can be accepted as definitely causative. Arkin and Wagner¹ state that 90 per cent of their patients were chronic smokers. They believe that inhalation of tobacco smoke may be an important factor in producing chronic irritation with epithelial metaplasia in the bronchi or bronchioles. The disease is preponderantly more common in males than in females, about two thirds of all cases occurring between the ages of 40 and 60. Occupation probably does not play an important part and evidence regarding the influence of preexisting pulmonary disease is not convincing. Edwards² emphasizes the fact that in a number of his patients the history was peculiarly free from illness in any form. A persistent cough, hemoptysis and thoracic pain of a severe and continuous type, in a man past the age of 40, are highly suggestive of pulmonary cancer. However, many of the cases of pulmonary carcinoma may be without pulmonary symptoms, their earliest manifestations being those of the metastases away from

the thoracic cage. Thus, in Arkin and Wagner's series of 135 cases, 51 per cent presented extrapulmonary signs and symptoms and only 49 per cent presented symptoms referable to the pulmonary tissue.

Recent histologic studies of malignant lesions of the lung have demonstrated that most of the round cell, "oat" cell and spindle cell sarcomas of the lung are in reality carcinomas of bronchogenic origin. The majority of the carcinomas of the lung are of the squamous cell type. Tuttle and Womack³ call attention to the faculty of the bronchial epithelium to change its morphologic characteristics when subjected to trauma or chronic irritation. The hyperplastic and metaplastic changes taking place may in reality be the first step in carcinogenesis. Attractive as this theory seems, it has found little support in clinical facts. Tuttle and Womack themselves state that of the seventy-six cases of primary bronchiectasis in persons of the cancer age seen in the chest service of the Barnes Hospital there has been observed only one patient who subsequently developed bronchogenic carcinoma. Bronchopulmonary carcinoma displays a tendency to give rise to metastases to the liver, bones, spleen, pancreas and, with a characteristic frequency, to the suprarenals and the brain. According to Tuttle and Womack, tumors of the major bronchi give symptoms early, extend more slowly and are more amenable to surgical treatment, while tumors of the minor bronchi and of the periphery of the lung cause fewer early symptoms and are more rapidly fatal.

As with the carcinomas elsewhere, the primary problem is that of early diagnosis. When one considers that x-ray examination of the chest alone is capable of rendering a correct diagnosis of carcinoma in not less than two thirds of all the cases, this problem should not be considered difficult. Bronchoscopic examination in the hands of an expert is valuable not only because it can visualize the tumor within the main bronchus but even more so because of the possibility of obtaining a biopsy specimen. According to Chevalier L. Jackson,⁴ bronchoscopic biopsy will be positive in about 75 per cent of the cases of bronchial carcinoma.

The therapeutic possibilities of bronchopulmonary cancer presented a rather hopeless outlook until the recent bold advances of thoracic surgery offered a ray of hope for at least the cases of a localized tumor before metastases have taken place. Most of the pulmonary carcinomas, including the squamous type, are radio-insensitive. Graham⁵ states that there is no record in the literature of successful radiotherapy of a single case in which the pathologic evidence has been incontrovertible and in which five year intervals without recurrence have elapsed between the treatment and the time of reporting the case, despite the fact that

many cases have been treated according to the most modern methods of using both x-rays and radium. There have been cases, however, in which surgical intervention has resulted in amelioration of symptoms as well as in at least temporary cures. These interventions have been principally lobectomies and occasional pneumonectomies. Graham successfully removed at one stage an entire left lung. Overholt⁶ removed the entire right lung. While the total number of pneumonectomies is small, probably not over a dozen, the future of the therapy of pulmonary cancer is not utterly hopeless.

RESEARCH IN DEMENTIA PRAECOX

Dementia praecox has been for many years the great unsolved problem in psychiatry. At present institutions for psychotic patients have a population of more than 400,000, and admissions seem to approximate 130,000 more each year. From time to time a glimmer of hope appears with the announcement of a new investigation which opens the path to a better understanding of some of the more serious psychiatric disorders and thereby the possible diminution of the number of patients demanding care. Thus the application of the results secured by Wagner-Jauregg has had a profound effect on the treatment of dementia paralytica. The time is yet too short to say with any certainty what will eventuate from the application of the use of insulin shock in the treatment of dementia praecox.

In a desire to be helpful in this field, where help is so greatly needed, the Supreme Council of the Scottish Rite Masons of the Northern Jurisdiction of the United States appropriated funds to be used in connection with research on dementia praecox. Approximately \$100,000 has already been allocated to assist in financing fourteen research projects approved by a scientific advisory committee.¹ As a first step in this work the committee determined to assemble the available medical periodical literature on the subject and to endeavor to correlate this material so as to obtain from the analysis suggestions or indications as to trends that might be useful in allocating additional funds for research. Unfortunately, this compilation of the available material seems to indicate a rather sterile past and does not apparently offer much in the way of indications as to logical opportunities for investigation in the future. This, in fact, would seem to be the conclusion reached by Prof.

Nolan D. C. Lewis,² since his final statement of conclusions indicates that the extensive work of the past and the thousands of articles that have been published yield little immediately applicable in the handling of the problem of dementia praecox. This should not, however, be reason for despair. Certainly it is valuable to know the character of the problem that confronts the investigator and the numerous blind alleys that have been followed by previous investigators.

The next step in the study of dementia praecox would seem to be an earnest taking of stock by those in whose hands the solution of the problem has been placed and the establishment of a systematic, well organized program of research based on the defining of problems the solution of which may form the basis for further study. The answer to the problem of dementia praecox will not perhaps be found along any single track of investigation. The histologist, the biologist, the student of metabolism, the psychiatrist and the psychoanalyst may each have a phase of this problem, which must be thoroughly studied before a real solution becomes apparent. Conceivably the basis of the disorder lies so deep in genetics that the answer must inevitably be prevention rather than cure. For the program, however, the medical profession may well look to the distinguished committee that has the problem in hand.

ANTIHEMORRHAGIC FACTOR IN FOODS

A new vitamin-like substance is apparently in process of gradual evolution. Its qualities are antihemorrhagic and tentatively it is called vitamin K. The substance is found in association with vitamin C (cevitamic acid) and can be separated from it. It is also obtained in relative abundance from alfalfa. Its structure is said to be complex; in concentrated form it is a colorless, unsaturated compound unstable to alcoholic alkalis even in the absence of air. Color tests indicate the presence of the indole nucleus, and analyses show a small nitrogen content with no trace of sulfur or phosphorus.³

The experimental data concerning this vitamin are derived for the most part from investigations on the chick. Szent-György² found striking differences between chicks made scorbutic by dietary deficiency which were given this vitamin and those which were not. The latter were shorter lived, lost more weight, had more fragile bones and showed more hemorrhages into the joints, intestine and muscles. These differences, Szent-György believed, were largely due to a specific influence on the capillary system.

Dam, Schönheyder and Lewis³ worked with ducklings, geese, pigeons and canaries; also with dogs, rats,

2. Bentsath, A.; Rusznyak, S., and Szent-Györgyi, A.: Vitamin Nature of Flavones, *Nature* 138: 798 (Nov. 7) 1936.

3. Dam, Henrik; Schönheyder, Fritz, and Lewis, Liese: The Requirement for Vitamin K of Some Different Species of Animals, *Biochem. J.* 31: 22 (Jan.) 1937.

guinea-pigs, rabbits and pigs. They studied the changes in clotting time of the blood from these animals following administration of the new factor under experimentally controlled conditions. Chicks and ducklings showed definite, positive responses, pigeons and canaries less. The results in mammals were inconclusive. The hemorrhagic diathesis produced in dogs by prolonged inanition they did not believe due to lack of this factor. They felt that the ability to dispense with it might be explained by lack of physiologic need for it in some species, by possible animal synthesis of the vitamin, or by synthesis of the vitamin by intestinal bacteria.

No real correlation to hemorrhagic diseases in man has as yet been adduced. However, hemophilia, scurvy and purpura offer fertile fields for research. In hemophilia the deficient functioning of the thrombocytes was pointed out earlier by Howell and Cekada, supplementing Howell's earlier theory regarding the rôle of prothrombin in blood clotting. The latter view was supported by the recent work of Patek and Taylor.⁴ In "vitamin K" avitaminosis it is prothrombin that is virtually absent, and the possible relationship between the two is of considerable interest.

Dam and his associates observed no beneficial effects from use of this factor in a case of hemophilia. Great caution is indicated in drawing conclusions from human cases of any type showing hemorrhagic symptoms. "Results" have been claimed for the use of everything from bee stings to autohemotherapy. In capable hands the exploration of the possibilities of this new vitamin may lead to the further elucidation of the mystery of the clotting of blood.

Previously, when vitamins were discovered, the tendency became international to name them alphabetically. However, with the further elucidation of vitamins and in particular the vitamin B complex, it becomes evident that this method of nomenclature is unscientific and should be discarded. Instead, the discoverer may well coin a name nontherapeutic in character and indicative of the composition. In line with this, the Council on Pharmacy and Chemistry of the American Medical Association has recently adopted the term riboflavin, which has been suggested by others, in preference to the term lactoflavin for vitamin G. The action of the Council regarding this matter was first referred to biochemists for comment. The Council has at present under consideration a name for pure vitamin B₁; while a number of names have been suggested, an agreement has not yet been reached by the discoverers of the crystalline vitamin B₁ and of synthetic vitamin B₁ with representatives of the Committee on Nomenclature or with the Society of Biological Chemists. The time is not too soon to begin thinking of some suitable scientific appellation for the evolving anti-hemorrhagic factor tentatively called vitamin K.

Some Properties of a Substance Obtained from Normal Human Plasma Effective in Accelerating the Coagulation of Hemophilic Blood, *J. Clin. Investigation* **16**: 113 (Jan.) 1937.

Current Comment

THE ARMY MEDICAL LIBRARY AND MUSEUM

In the Army Medical Library and Museum in Washington, D. C., are housed some of the finest collections available in the field of medicine. The library now contains some 400,000 bound and unbound books and approximately 600,000 pamphlets and periodicals. Included in this material are about 450 incunabula of the total 600 in existence. This library and its Index Catalogue have been recognized everywhere as among the greatest of bibliographic facilities in the world. The House of Delegates of the American Medical Association has repeatedly gone on record as favoring a new building to house these invaluable collections. The present building was constructed in 1887 and the contents of both the library and the museum have outgrown their accommodations. Whether the Army Medical Library and Museum building is erected on the site of the Army Medical Center to round out that institution, which includes the Walter Reed General Hospital, the Army Medical, Dental and Veterinary Schools and the Biological Laboratory, or is to adorn one of the beautiful parkways or drives elsewhere in Washington is really not the vital consideration. The need for a new building is pressing. The construction of such a building would give opportunity for modernizing the equipment and making the materials far more available than they are now. It would serve as a monument to medicine in consideration of its services to human welfare.

MORE MEDICAL MISINFORMATION FROM CONSUMER'S RESEARCH

Consumer's Research, which formerly limited its publications largely to the confidential bulletin circulated among its subscribers, now comes forth with *Consumers' Digest*, published by Editor Schlink with a view, no doubt, to reaching a larger audience. An article on "Diet and Common Colds" again emphasizes the inherent fallacy of discussions of medical subjects by untrained writers. This article calls attention to "an important study" by Frederick Hoelzel. Some comments by Hoelzel were reported briefly in *Science* in 1928 when he was a guest investigator in the Department of Physiology of the University of Chicago. He then wrote that observations over a period of years on one subject, himself, suggested a relation between diet and the incidence of colds. Hoelzel had on several occasions practiced periods of fasting. He remained in good health while fasting but invariably contracted a cold when he resumed eating. He reasoned that the diet affected the degree of hydration of the tissues, which in turn was related to susceptibility to colds. High carbohydrate diets increased hydration and susceptibility, and high fat diets decreased both, he thought. Contrary to substantial evidence, Hoelzel suggested that the relative freedom of arctic explorers from colds is due to the decreased carbohydrate intake rather than to the absence of bacteria. In 1934 Hoelzel

wrote "I have abandoned the idea of using a high fat diet, such as I advocated in 1928, for the prevention of colds and nutritional hydration." This second article was ignored by the article in *Consumers' Digest*, which states that a diet consisting of adequate protein with a minimum of carbohydrate "proved to be" the most efficacious in the prevention of colds, while a diet high in carbohydrate with a restricted protein intake was accompanied by difficulty with colds. The recommended diet for the prevention of colds would consist of liberal portions of lean meat, poultry, fish, cheese, eggs and other animal products, with a restricted intake of potatoes, corn, beans, cereal, pastry, candy, syrup, soft drinks, ice cream, sherbet, alcoholic liquors, sweet fruits and—of all things—fruit juices. Again, apparently without adequate consultation with medical authority, and this time even without adequate survey of recently available evidence, Consumer's Research presumes to dispense bad medical advice to its perhaps too trusting readers.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

CALIFORNIA

Society News.—The San Francisco County Medical Society devoted its April 13 meeting to a symposium on splenic disease at which the speakers were Drs. Stacy R. Mettler, Salvatore P. Lucia, H. Brodie Stephens, Leo Henry Garland and Zera E. Bolin.—Dr. Robert W. Lamson, Los Angeles, addressed the San Diego County Medical Society, April 13, on "Allergy, Its Application in General Practice."

Bust of Dr. Widney.—A bust of Dr. Joseph P. Widney was presented to the library of the Los Angeles County Medical Association, May 11. Dr. Widney, who is 95 years of age, was present at the ceremonies. He was the founder of the College of Medicine of the University of Southern California and dean and professor of medicine on its faculty for many years. He was president of the University of Southern California from 1892 to 1895.

Dr. Hoffmann Lectures on Syphilis.—Dr. Erich Hoffmann, professor of dermatology and syphilology, University of Bonn, Germany, addressed the faculty and students of Stanford University School of Medicine, San Francisco, April 13, on congenital syphilis, and a special meeting of the San Francisco County Medical Society, April 16, on efforts and attainments in the early treatment of syphilis. He addressed the Los Angeles Dermatological Society, April 5, on *Spirochaeta pallida* and the early investigation of the arsphenamines by Ehrlich; at a special meeting he was elected an honorary member of the society. In San Francisco Dr. Hoffmann was given the "key to the city" by Mayor Rossi and made honorary president of the San Francisco Dermatological Society.

COLORADO

Society News.—Dr. George W. Crile, Cleveland, addressed a joint banquet of the Medical Society of the City and County of Denver and the staff of Children's Hospital, April 6.—The Mesa County Medical Society was addressed in Grand Junction, April 20, by Drs. Edward E. H. Munro on "Intestinal Obstruction"; Guy C. Cary, "Superstition in Treatment of Diseases of the Eye," and Herman C. Graves, "Orthostatic Albuminuria."—Dr. Robert H. Fitzgerald, Leadville, read a paper on "Physiology, Pathology and Treatment of Edema of the Brain" before the Prowers County Medical Society in Lamar, April 6.—At a meeting of the Northwestern Colorado Medical Society in Steamboat Springs, March 25, Dr. William W. Sloan, Mount Harris, discussed the "Roger Anderson Method of Reduction and Treatment of Fractures."

CONNECTICUT

State Medical Meeting at Bridgeport.—The one hundred and forty-fifth annual meeting of the Connecticut State Medical Society will be held at Bridgeport, May 19-20, with headquarters at the Hotel Stratfield and under the presidency of Dr. Daniel C. Patterson, Bridgeport. Included on the program are the following:

- Dr. Howard A. Kelly, Baltimore, *Reminiscences in the Development of Gynecology.*
- Dr. Porter P. Vinson, Richmond, Va., *Diagnosis and Treatment of Primary Malignant Disease of the Tracheobronchial Tree.*
- Dr. George Levene, Boston, *Value of Roentgenologic Study in the Diagnosis of Heart Disease.*
- Dr. Elias W. Abramowitz, New York, *Eruptions Caused by Commonly Used Drugs.*
- Dr. Allan K. Poole, New Haven, *Conservative Treatment of Syphilis.*
- Dr. John Homans, Boston, *Symptomatology of Surgical Diseases of the Anus and Rectum.*
- Dr. Charles Sidney Burwell, Boston, *Factors in the Treatment of Asymptomatic Period of Heart Disease.*
- Dr. David Weisberger, Boston, *Studies in Vitamin C Content of Blood in Patients with Dental Abnormalities.*
- Dr. Samuel J. Kopetzky, New York, *Clinical Picture of Suppurative Lesions of the Petrosal Pyramid.*
- Dr. Clyde E. McDannald, New York, *Practical Points in Operative Surgery of the Eye.*
- Dr. Foster Kennedy, New York, *The Paranoiac in Court.*
- Dr. Ralph M. Tovell, Hartford, *Preliminary Report on the Reorganization of the Section on Anesthesia, Hartford Hospital.*
- Dr. Louis S. Goodman, New Haven, *Chemical Mediation of Nerve Stimuli.*
- Dr. Brian C. Sword, New Haven, *Analysis of Peridural Anesthesia as Employed at Grace Hospital.*

James Rowland Angell, president of Yale University, New Haven, will speak at the annual dinner of the society Wednesday evening. Hon. Meier Steinbrink, justice of the Supreme Court, New York, will address a dinner meeting of the section on neurology and psychiatry on "The Medical Witness." At a luncheon Wednesday, Dr. Catharine Macfarlane, Philadelphia, will discuss "Carcinoma Developing in the Uterus After Irradiation Menopause" before the Women's Medical Society of Connecticut. Thursday afternoon Alexander O. Gettler, Ph.D., New York, will address the Connecticut Medical Examiners Association on "Toxicology in Medical Legal Autopsy" and Dr. Parker Dooley, New York, the Hezekiah Beardsley Pediatric Club on "Bacillary Dysentery in Childhood." A special session of the American Society of Anesthetists will conclude the day's program. The annual secretaries' conference will be held Thursday at a luncheon session.

ILLINOIS

Personal.—Dr. Eli G. Davis, Lewistown, was guest of honor at a dinner, February 15, to celebrate his eighty-fourth birthday.—Dr. Robert R. Smith has resigned as superintendent of the Kankakee State Hospital, Kankakee, to return to private practice, it is reported. Dr. George W. Morrow is acting head of the institution.

Society News.—Dr. Clarence F. G. Brown, Chicago, addressed the Lake County Medical Society, April 12, on medical management of intractable ulcer and medical management of low grade gallbladder disease.—The St. Clair County Medical Society was addressed in Belleville, April 7, by Drs. Duff S. Allen and Cyril M. MacBride, both of St. Louis, on surgical treatment of toxic goiter and borderline goiter conditions respectively. Dr. Willard C. Scrivner addressed the East St. Louis meeting, April 1, on cancer of the uterus.—Constituent societies of the eighth district were addressed, April 7, by Drs. Winston H. Tucker and Paul H. Harmon, both of the state department of public health, and Harold M. Camp, Monmouth, secretary, Illinois State Medical Society, on the social security act.

Chicago

Hospital News.—There is a residency open in physical therapy at Michael Reese Hospital, effective July 1. Applicants must be graduates of class A schools and must have completed their internship. Additional information may be obtained from Dr. Charles O. Molander at the hospital.

Study of Eclampsia Cases.—Dr. Joseph B. De Lee wishes to obtain two or three cases of eclampsia for a motion picture. The patients may be sent to the Chicago Lying-In Hospital, where the physician may continue his own treatment. No charge for hospital care or ambulance will be made.

Branch Society Meetings.—The North Side Branch of the Chicago Medical Society held its annual May party at the Lake Shore Athletic Club, May 6. Dr. Frank P. Thompson showed motion pictures of "An African Hunting Trip." Dr. Reed M. Nesbit, Ann Arbor, discussed "Water Requirements of the Surgical Patient" before the Aux Plaines Branch April 23. At a meeting of the South Chicago Branch, April 27, Dr. Wilber E. Post spoke on "Nephrosis and Nephrotic

Edema." A symposium on low back pain was presented before the Douglas Park Branch, April 20, by Drs. Maurice I. Kaplan, Edward L. Cornell, Edward W. White and Felix M. Jansey.

IOWA

Annual Renewal Fees Due Before June 1.—All licenses to practice medicine and surgery in Iowa expire annually on June 30. To renew such a license a licentiate must make a written application to the state department of health before June 1, enclosing the renewal fee of \$1. If a license expires by reason of the licentiate's failure to renew it, it can be reinstated without reexamination only on the recommendation of the state department of health and the payment of the overdue fees.

Central District Meeting.—The annual meeting of the Iowa and Illinois Central District Medical Association will be held at the Outing Club, Davenport, May 27. The following program will be presented: Drs. French K. Hansel, St. Louis, "Allergy"; Walter C. Alvarez, Rochester, Minn. (subject to be announced); Arthur E. Hertzler, Halstead, Kan., "Surgery of the Thyroid," and William W. Bauer, Director, Bureau of Health and Public Instruction, American Medical Association, Chicago, "Popular Beliefs That Are Not So."

University Offers Services of Pediatrician.—The department of pediatrics of the University of Iowa College of Medicine, Iowa City, has placed the services of a staff member, Dr. Mark W. Dick, at the disposal of the speakers' bureau of the state medical society. Dr. Dick will speak before county medical societies on pediatric subjects. At afternoon meetings he will examine any medically crippled child (diabetic and cardiac). For the afternoon meetings the following rules have been formulated: the work will be undertaken only at the request of the county medical society, and under the direction of the family physician, and will be available for children in indigent families only.

KANSAS

Personal.—Dr. Charles E. Vestle, Holton, has been appointed physician for the Kansas state prison at Lansing. —Dr. Albert G. Smith, Oskaloosa, was guest of honor at a dinner given by the Shawnee County Medical Society at Topeka, April 5, in celebration of his completion of fifty years in the practice of medicine. —Dr. David W. Basham, Wichita, was recently named president emeritus of the Sedgwick County Medical Society, in recognition of his many years of service in the community. Dr. Basham has been in practice in Kansas for fifty-four years. He was president of the society in 1917. —Dr. Edwin M. Ireland, Coats, has been appointed health officer of Pratt County, succeeding Dr. Charles E. Phillips. —Dr. Theodore W. Weaver has been named mayor of Wichita.

MAINE

The Frederic Henry Gerrish Library.—A circulating library has been created at the Central Maine General Hospital, Lewiston, through a grant of the Bingham Associates in honor of the late Dr. Frederic Henry Gerrish, who was at one time professor of anatomy at Bowdoin College Medical School, Portland. Material in the library, which now contains seventy-five journals together with a large collection of reprints, will be available to all members of the state medical association. Dr. Gerrish received his degree of doctor of medicine from Bowdoin in 1869 and practiced in Portland from 1870 until his death in 1920. He was professor of materia medica and therapeutics until 1882 and professor of surgery from 1905 to 1911. He was president of the Maine Medical Association, 1901-1902, and of the American Therapeutic Society, 1908-1909.

MARYLAND

Personal.—Drs. LeGrange B. Byington, surgeon, U. S. Public Health Service, in charge of the Baltimore Quarantine Station at Curtis Bay, and Dr. Roy R. Jones, passed assistant surgeon of the service, assigned to the division of labor standards of the U. S. Department of Labor, have been appointed members of the advisory committee on sanitation of the Baltimore City Health Department. Dr. Byington will fill the vacancy created when Dr. Harry F. White was transferred from the local quarantine station, according to *Baltimore Health News*.

Dr. Mustard to Succeed Dr. W. H. Park.—Dr. Harry Stoll Mustard, associate professor of public health administration in the School of Hygiene and Public Health, Johns Hopkins University, Baltimore, has been appointed Hermann

M. Biggs professor of preventive medicine and director of the laboratories of preventive medicine at New York University College of Medicine, succeeding Dr. William H. Park, who retired last year. Dr. Mustard formerly was connected with the U. S. Public Health Service, and he went to Tennessee in 1924 as director of the child health demonstration of the Commonwealth Fund at Murfreesboro. In 1932 he resigned as director of health education and of child hygiene and public health nursing in the Tennessee State Department of Health to take charge of the newly created public health district in Baltimore, under the auspices of the Rockefeller Foundation and the Johns Hopkins School of Hygiene and Public Health.

MICHIGAN

Annual Clinic at Lansing.—The Ingham County Medical Society held its annual clinic at the Hotel Olds, Lansing, April 29. The following speakers were on the program:

- Dr. Francis E. Seneor, Chicago, Diagnosis and Treatment of Early Syphilis.
- Dr. Joseph L. Miller, Chicago, Treatment of Nephritis.
- Dr. Chevalier L. Jackson, Philadelphia, Postoperative Pulmonary Complications.
- Dr. Herbert W. Meyer, New York, Excursions into Fields of Surgery.
- Dr. Alfred A. Strauss, Chicago, Surgical Treatment of Peptic Ulcer.

Michigan Deaths from Automobile Accidents.—Automobiles were responsible for the deaths of 1,891 persons in Michigan in 1936, setting a new record for this cause of death, according to the state medical journal. This total gave a 13 per cent increase over the rate for 1935, when 1,667 persons were killed. More than 200 persons were killed during each of the last four months of the year, giving an average of at least seven deaths a day, while the highest monthly total, 223, was reported for December.

Annual Joint Concert.—The symphony orchestra and the glee club of the Wayne County Medical Society presented the following program at their annual joint concert in the main auditorium of the Detroit Institute of Art, April 26:

Georges Miquelle, Conducting

1. SAINT-SAENS Marche Heroique
2. DEBUSSY En Bateau
- DEBUSSY Minuet
- JARNEFELT Prælude
3. A.
 - (1) PRAYER OF THANKSGIVING.....Kremser
 - (2) THE BELLS OF ST. MARYS
 - B.
 - (1) OLE MAN RIVER.....Jerome Kern
 - (2) ON THE ROAD TO MANDALAY.....Oley Speaks

Marcus Kellerman—Director
Henry Brown, M.D.—Accompanist
4. SAINT-SAENS Danse Macabre
5. GOUNOD Ballet of Faust
6. GUION Alley Tunes
7. DVORAK Going Home
- GRIEG Landslighting

Glee Club and Orchestra

8. BERLIOZ Hungarian March

MINNESOTA

Personal.—Dr. Leo M. Maguire has been appointed in charge of the Fort Snelling Veterans' Administration Facility, succeeding Dr. Warren A. Colton, who has been transferred to Hampton, Va.

State Medical Election.—Dr. James M. Hayes, Minneapolis, was elected president of the Minnesota State Medical Association at its recent annual meeting in St. Paul, to take office Jan. 1, 1938. Drs. William R. McCarthy, St. Paul, and Baxter A. Smith, Crosby, were chosen vice presidents, and Drs. Edward A. Meyerding, St. Paul, and William H. Condit, Minneapolis, were reelected secretary and treasurer respectively. Dr. Meyerding has been secretary since 1924.

Society News.—Dr. Lewis M. Daniel, Minneapolis, addressed the Minnesota Academy of Medicine, recently, in Minneapolis, on "Pneumonic Pathology in the Upper Lung Fields." Dr. Alexander R. Colvin, St. Paul, presented a case report on twenty-eight years of surgical pathologic conditions in one patient. —The Hennepin County Medical Society was addressed in Minneapolis, March 31, by Dr. Albert M. Snell, Rochester, on "Diagnostic Problems in Diseases of the Liver and Biliary Tract." Dr. Henry S. Ruth, Philadelphia, spoke before the society, recently, on "Physiology of Anesthesia," and Charles H. Rogers, Sc.D., dean, University of Minnesota College of Pharmacy, "Interprofessional Relations—Is There a Policy?" —The Minneapolis Surgical Society was addressed, March 4, by Drs. Arthur A. Zierold on "Closure of Abdominal Wounds" and James M. Hayes, "Advisability of Informing School Children Concerning the Common Symptoms of Appendicitis."

NEW MEXICO

New State Health Officer.—Dr. Edwin B. Godfrey, San Bernardino, Calif., has been appointed state health officer of New Mexico to succeed Dr. John Rosslyn Earp, resigned. Dr. Godfrey was health officer of Santa Fe County for several years before his appointment to a similar position in San Bernardino County. He is 55 years old and was graduated from Miami Medical College, Cincinnati, in 1909. Dr. Earp became state director of health Jan. 1, 1930.

NEW YORK

State Medical Meeting at Rochester.—The one hundred and thirty-first annual meeting of the Medical Society of the State of New York will be held in Rochester, May 24-26, at the Rochester Chamber of Commerce. The scientific sessions will be held Tuesday and Wednesday, with section meetings in the mornings and general sessions in the afternoons. At the general session Tuesday a symposium on "The Relief of Intractable Pain" will be presented by Drs. James C. White, Boston, and Byron P. Stookey and Louis Casamajor, New York. Wednesday there will be a symposium on "The Blood" by Drs. William B. Castle, Boston; Cyrus C. Sturgis, Ann Arbor, Mich., and George H. Whipple, Rochester. Invited guests who will address the sections include:

Dr. Walter R. Campbell, Toronto, Uses of Protamine Zinc Insulin.
Dr. Norman F. Miller, Ann Arbor, Mich., Vesicovaginal Fistulae, Their Cause and Cure.
Dr. Louis K. Diamond, Boston, Iron Deficiency Anemia in Infants and Children.
James B. Hamilton, Ph.D., Albany, Cryptorchidism.

There will be two special sessions, one on regional and general anesthesia and one on physical therapy. In the first the speakers will be Drs. Orville C. King, Philadelphia; Emery A. Roventine, New York; Philip D. Woodbridge, Boston, and Wesley Bourne, Westmount, Que. In the second the speakers include Mr. Howard A. Carter, secretary of the Council on Physical Therapy, American Medical Association, Chicago; Drs. Karl Harpuder, New York; Jacob Gutman, Brooklyn; Richard Kovacs, New York, and George G. Martin, Buffalo. Entertainment includes a golf tournament Thursday afternoon at the Oak Hill Country Club, visits to Bausch and Lomb and the Eastman Kodak Company, and the annual banquet at the Chamber of Commerce Tuesday evening. The woman's auxiliary will hold its annual meeting under the presidency of Mrs. John L. Bauer, Brooklyn.

New York City

Sir Henry Dale to Give Harvey Lecture.—Sir Henry H. Dale, director of the National Institute for Medical Research, London, will deliver the eighth Harvey Society Lecture of the current series at the New York Academy of Medicine, May 20, on "Transmission of Nervous Effects by Acetylcholine."

Cornell Alumni Meeting.—The annual "Spring Day" meeting of the Cornell University Medical College Alumni Association was held April 29. Various departments were open to visitors during the day, and in the afternoon a special feature was a symposium on occupational diseases, with the following speakers:

Dr. Paul Reznikoff, Distinction Between Lead Absorption and Lead Poisoning.
Frederick B. Flinn, Ph.D., Obscure Symptoms in Lead Poisonings.
Dr. Niel E. Eckelberry, Acute Carbon Monoxide Poisoning.
Alexander O. Gettler, Ph.D., Importance of Carbon Monoxide Determinations in Forensic Medicine and Disability Claims.

Dr. Anthony J. Lauza presided at the symposium and Dr. William S. Ladd, dean of the medical school, summarized the discussion. A banquet was held at the Biltmore in the evening, at which the speakers were Drs. Livingston Farrand, who retires this year as president of the university; Charles G. Heyd, President of the American Medical Association, and Floyd S. Winslow, Rochester, president of the Medical Society of the State of New York.

One Year Study of Self-Inflicted Deaths.—A comprehensive one year study of self-inflicted deaths in the New York area has been begun by New York University College of Medicine under the direction of Dr. Nathaniel Ross, assistant clinical professor of psychiatry, and under the supervision of Dr. Karl M. Bowman, director of the psychiatric division of the department of hospitals, Dr. Gregory Zilboorg, director of research for the Committee for the Study of Suicide, and Dr. John Wyckoff, dean of the college. Dr. Ross and his staff will have at their command the clinical material at Bellevue Hospital, among whose patients are about 1,500 each year who have attempted to take their own lives. The research group will consist of about fifty psychiatrists and social work-

ers. The Committee for the Study of Suicide was organized in 1936 (THE JOURNAL, Feb. 29, 1936, p. 713) by a group of psychiatrists and other citizens to study the causes of and the contributing factors to suicide, to standardize methods for the treatment and prevention of suicidal drives in both the adult and the adolescent, and to discover any bearing that social crises such as depressions, wars and revolutions may have on suicidal trends. Dr. Gerald R. Jamieson is president; Dr. Henry Alsop Riley, vice president, and Dr. Zilboorg, secretary and director of research.

NORTH CAROLINA

Dr. McBrayer Resigns as State Secretary.—Dr. Louis B. McBrayer, Southern Pines, has resigned as secretary and treasurer of the Medical Society of the State of North Carolina and Dr. Thomas W. M. Long, Roanoke Rapids, has been appointed to succeed him. Dr. McBrayer has been made honorary secretary for life. A native of North Carolina, Dr. McBrayer graduated at the University of Louisville School of Medicine (1889). From 1901 to 1907 he was coroner of Buncombe County, from 1909 to 1914 health officer of Asheville. From 1914 to 1924 he was superintendent of the North Carolina State Sanatorium for the Treatment of Tuberculosis and was active in organizing the fight against tuberculosis in the state. He has been managing director of the North Carolina Tuberculosis Association since 1915. In 1925-1926 he was president of the Southern Conference on Tuberculosis and served as president of the state board of medical examiners from 1908 to 1914. Dr. McBrayer served as president of the state medical society at one time and has been secretary and treasurer for twenty-one years. In appreciation of his service, the society gave a dinner in his honor and presented him with a silver service. Speakers were Drs. Addison G. Brenizer, Charlotte; William H. Smith, Goldsboro; Grady G. Dixon, Ayden, and William M. Coppridge, Durham. Dr. Paul H. Ringer, Asheville, was toastmaster. Dr. Long is a native of North Carolina, took his medical degree at the Medical College of Virginia in 1908 and has practiced in Roanoke Rapids since 1910. He is a former president of the Halifax County Medical Society and of the fourth district society. He was a member of the state board of medical examiners from 1927 to 1932. He has served several terms in the state legislature and has been mayor of Roanoke Rapids.

NORTH DAKOTA

State Medical Meeting at Grand Forks.—The fiftieth annual session of the North Dakota State Medical Association will be held at Grand Forks, May 16-18, under the presidency of Dr. William A. Gerrish, Jamestown. Speakers will include:

Dr. Willard A. Wright, Williston, Treatment of Burns with Demonstration of Rapid Tanning Method by Natural Color Motion Pictures.
Dr. Donald C. Balfour, Rochester, Minn., Problems in the Diagnosis and Treatment of Gastro-Intestinal Hemorrhage.
Dr. Henning M. Berg, Bismarck, Cancer.
Dr. George A. Williamson, St. Paul, Minn., Fractures of the Upper Extremity.
Dr. Edward L. Tuohy, Duluth, Bone Marrow: Its Vital Importance to the Body.
Dr. William H. Long, Fargo, The Management of Nephritis.
Dr. Reuben H. Waldschmidt, Bismarck, Initial Care and Treatment of Accidental Injuries.
Dr. Robert D. Mussey, Rochester, Minn., Course, Conduct and Complications of Pregnancy Among Physicians' Wives.
Dr. John S. Lundy, Rochester, Minn., Anesthesia and Relief of Pain by the General Practitioner.
Dr. Kent E. Darrow, Fargo, Problems in the Diagnosis of Obstruction in the Bowel.
Dr. Reinhold O. Goehl, Grand Forks, Protamine Insulin.

Dr. Tuohy will be the principal speaker at the annual banquet Monday evening. The North Dakota Health Officers' Association will meet Tuesday afternoon. At a luncheon session, Dr. Calvin C. Applewhite, Chicago, U. S. Public Health Service, will discuss "Present Trends in Public Health Administration." In the afternoon the following speakers will participate in a symposium on venereal diseases: Drs. Harry G. Irvine, Minneapolis; Leonard W. Larson, Bismarck; Paul A. O'Leary, Rochester, Minn., and Kenneth F. Maxcy, Minneapolis. Monday afternoon Dr. Arthur E. Smith, Los Angeles, will address the North Dakota Academy of Ophthalmology and Otolaryngology on "Reconstructive and Plastic Oral Surgery."

PENNSYLVANIA

Personal.—Dr. Don Marshall, assistant professor of ophthalmology, University of Michigan Medical School, Ann Arbor, Mich., has been appointed director of the department of ophthalmology at the George F. Geisinger Memorial Hospital, Danville.—Dr. Persis R. S. Robbins, Bradford, has been appointed medical director of McKean County, succeeding Dr. James M. Rodgers, Smethport.—Dr. Jacques P. Gray,

assistant director of public safety, San Francisco, has been appointed health officer of Wilkes-Barre and manager of the Kirby Memorial Health Center.

Philadelphia

Dr. Lange Appointed Professor of Bacteriology.—Dr. Linda B. Lange, associate professor of bacteriology at Johns Hopkins University School of Hygiene and Public Health, has been appointed professor of bacteriology and immunology at the Woman's Medical College of Pennsylvania, effective in July. Dr. Lange was graduated from Johns Hopkins University School of Medicine in 1911, was fellow in pathology at the Rockefeller Institute for Medical Research, New York, 1912-1914, and pathologist at the Howard A. Kelly Hospital, Baltimore, 1914-1915. She was instructor in pathology at the University of Wisconsin Medical School, 1915-1916, and instructor in medicine at Johns Hopkins, 1916-1918.

Pittsburgh

Behavior Clinic in Criminal Courts.—A behavior clinic was established May 1 in the criminal courts of Allegheny County, with Dr. James M. Henninger, Woodville, as chief psychiatrist and Dr. Edward J. Carroll Jr. as assistant. The board of judges of the common pleas court, in announcing the appointments, made the following statement: "By means of this clinic there will be made available to the judges a detailed study that should materially help in the proper administration of justice. It will guarantee a better protection for the public interest and a more humane treatment of those who, by reason of physical or mental disability, should not be treated as the ordinary offender who is making war on society." Judges Ralph H. Smith, James H. Gray and William H. McNaugher make up a permanent committee in charge of the clinic, and the following physicians have been appointed to an advisory committee: Drs. Edward E. Mayer, George Wright and William Shapera. Dr. Henninger, who is the son of Dr. Charles H. Henninger, professor of psychiatry at the University of Pittsburgh School of Medicine, is a graduate of that school and served for two years on the staff of the Torrance State Hospital and a year as psychiatrist at the Allegheny County Home. Dr. Carroll is also a graduate of the University of Pittsburgh and is chief resident in psychiatry at St. Francis Hospital.

SOUTH DAKOTA

State Medical Meeting at Rapid City.—The annual meeting of the South Dakota State Medical Association will be held in Rapid City, May 24-26. Tuesday morning there will be clinics by the following guests: Drs. Albert M. Snell, Rochester, Minn., medical; Myron O. Henry, Minneapolis, orthopedic; Claude F. Dixon, Rochester, surgical, and George E. Robertson, Omaha, pediatric. Wednesday morning has been reserved for a trip to the Black Hills. The South Dakota Academy of Ophthalmology and Otolaryngology will meet, May 25, with the following speakers: Drs. Avery D. Prangen, Rochester, "Diagnosis and Treatment of Strabismus"; Joseph J. Hompes, Lincoln, Neb., "Moot Questions in Cataract Surgery," and Harry B. Stokes, Omaha, "Significance of Chronic Hoarseness."

TENNESSEE

Personal.—Dr. Marion S. Lombard, medical officer in charge of the U. S. Marine Hospital, Memphis, has been transferred to the Marine Hospital at Buffalo. Dr. Edwin H. Carnes, now at the hospital at Key West, Fla., will succeed Dr. Lombard.—Dr. Don C. Peterson, formerly of Austin, Texas, has been appointed health officer of Williamson County to succeed Dr. Robert Knox Galloway, Franklin, resigned.

State Medical Election.—Dr. George C. Williamson, Columbia, was elected president of the Tennessee State Medical Association at the annual meeting in Knoxville, April 13-15. Vice presidents were elected as follows: Drs. Andrew Smith, Knoxville, for East Tennessee; Jack Witherspoon, Nashville, for Middle Tennessee, and Fred K. West, Rossville, for West Tennessee. Dr. Harrison H. Shoulders, Nashville, was reelected secretary-editor.

VIRGINIA

Society News.—The Southwestern Virginia Medical Society held its spring meeting in Pulaski, April 8-9, with Dr. Emil Novak, Baltimore, as the guest speaker, on "The Endocrine Basis of Gynecological Organotherapy."—Dr. William B. Castle, Boston, addressed the Norfolk County Medical Society, Norfolk, March 15, on "Treatment of Anemia from the Standpoint of the General Practitioner."—At the quar-

terly meeting of the Southside Virginia Medical Society in Franklin, March 9, the speakers included Drs. Paul D. Camp, Richmond, on "Treatment of Congestive Heart Failure"; Otis L. Anderson, Richmond, "Problems of Early Syphilis," and Charles S. Dodd, Petersburg, "Glaucoma and Optic Atrophy."

WEST VIRGINIA

State Medical Meeting May 24-26.—The seventieth annual meeting of the West Virginia State Medical Association will be held in Clarksburg, May 24-26, with headquarters at the Stonewall Jackson Hotel. Guest speakers who will address general and sectional meetings are:

Dr. Dean D. Lewis, Baltimore, Surgical Problems of the Ductless Glands.
Dr. Horton R. Casparis, Nashville, Mental Health of Children; Pediatric Responsibility in Health Education.
Dr. Louis F. Bishop Jr., New York, Prevention of Heart Disease; Fugitive
Dr. Ralph " " Toxic Effects of Carbon Dioxide.
Dr. Norri " " Vaginal Bleeding in the Last Trimester of Pregnancy.
Dr. Moses Paulson, Baltimore, Newer Aspects of Gallbladder Disease of Practical Import.
Dr. John Huber Wagner, Pittsburgh, Treatment of Fractures.
Dr. deWayne G. Richey, Pittsburgh, Diagnosis and Treatment of Inflammatory Lesions of the Oropharynx.

Dr. Thomas Parran, surgeon general, U. S. Public Health Service, Washington, D. C., will be the speaker at the annual banquet Wednesday, May 26, at the Waldo Hotel, on "Public Health Control of Syphilis." Several of the guest speakers will address special societies that will meet during the week. These include the West Virginia Heart Association, West Virginia Society of Obstetricians and Gynecologists and the West Virginia Society of Industrial Physicians and Surgeons. Dr. Lester Hollander, Pittsburgh, will be a guest of the latter society, speaking on "Diagnosis and Treatment of Industrial Dermatoses." Dr. Oscar B. Biern, Huntington, will deliver the annual oration in medicine, on "The Value of the Sedimentation Rate in Medicine"; Dr. Benjamin H. Swint, Charleston, the oration in surgery, on "Pain in Abdominal Crisis." Dr. William S. Fulton, Wheeling, will deliver his official address Tuesday evening. The woman's auxiliary will hold its thirteenth annual meeting during the association's meeting. The auxiliary has arranged an exhibit of physicians' hobbies, the first the association has had.

WISCONSIN

Personal.—Dr. Rollin D. Thompson, superintendent of the Wisconsin State Sanatorium, Statesan, recently resigned to become superintendent of a new hospital now nearing completion at Orlando, Fla., it is reported.—Dr. Carl N. Neupert, Janesville, has been appointed assistant state health officer. He succeeds Dr. Ethan B. Pfefferkorn, Oshkosh, who resigned to reenter private practice.—Dr. Robert L. MacCornack, Whitehall, has been appointed a member of the state board of health.—Dr. Willard M. Sonnenburg was elected mayor of Sheboygan for his third term April 6.

Society News.—Dr. Solon Marx White, Minneapolis, among others, addressed the Eau Claire-Dunn-Pepin County Medical Society, recently, in Eau Claire, on "Diagnosis and Management of Acute Myocardial Damage of Vascular Order."—Dr. John E. Gonce Jr., Madison, addressed the Fond du Lac County Medical Society, Fond du Lac, recently, on "Use of Various Serums and Vaccines in the Diagnosis and Treatment of Infectious Diseases."—Dr. Joseph Brennemann, Chicago, gave the Lippitt Memorial Lecture of the Milwaukee County Medical Society, Milwaukee, March 12, on acute abdominal conditions in children.

PHILIPPINE ISLANDS

Society News.—Speakers at a meeting of the Manila Medical Society, January 12, were Drs. Miguel Canizares, on surgery of pulmonary tuberculosis; Walfrido de Leon and Alfredo Pio de Roda, tropical typhus in the Philippines.—Dr. Mariano B. Lara, among others, addressed the Culion Medical Society, January 24, on pseudohemagglutination in leprosy and certain other diseases and its relation to erythrocyte sedimentation.

Personal.—Dr. Leoncio Lopez-Rizal, chief of the administrative division of the bureau of health of the Philippines, retired February 10 after twenty-five years in the government service.—Dr. Antonio G. Sison, recently named dean of the University of the Philippines College of Medicine, has been appointed director also of the school of hygiene and public health. Dr. Hilario Lara was made assistant director. Dr. Carmelo M. Reyes has been appointed chief of clinics and head of the department of gynecology, and Dr. Jose Albert head of a newly created department of clinical studies and research.

GENERAL

Meetings in Atlantic City.—The annual meeting of the Medical Women's National Association will be at the Chalfonte, Atlantic City, June 6-8. Among the speakers will be Drs. Elizabeth Mason Hohl, Los Angeles, on the "Campaign Against Cancer," and Bertha Van Hoosen, Chicago, on "Maternal Mortality." Dr. Mabel M. Akin, Portland, Ore., will be installed as president. —The board of chancellors of the American College of Radiology will hold its regular annual meeting in Atlantic City, June 8, at Haddon Hall. Dr. Edward L. Jenkinson, 2561 North Clark Street, Chicago, is executive secretary of the college. —Phi Alpha Sigma Medical Fraternity will hold a luncheon meeting in the Fountain Room of the Shelbourne Hotel, Atlantic City, June 9.

American Laryngological Association.—The fifty-ninth annual congress of the American Laryngological Association will be held at the Marlborough-Blenheim, Atlantic City, May 31-June 2. The following, among other speakers, will be on the program:

Dr. Chevalier Jackson, Philadelphia, Benign Tumors of the Larynx.
Dr. Thomas E. Carmody, Denver, Cysts of the Mandible.
Dr. George M. Coates, Philadelphia, Cholesteatoma of the Frontal Sinus.
Dr. Ralph Albert Fenton and Olof Larsell, Ph.D., Portland, Ore., The Defense Mechanisms of the Upper Respiratory Tract.
Dr. John D. Kernan, New York, Use of Helium Oxygen Therapy in Obstructive Lesions of the Air Passages.

The president, Dr. William B. Chamberlin, Cleveland, and his wife will hold an informal reception Monday evening, and the annual banquet will be given Tuesday evening.

Meeting of Otological Society.—The American Otological Society will hold its seventieth annual meeting at the Lido Country Club, Long Beach, Long Island, N. Y., May 27-28. Most of the meeting will be devoted to a symposium on the neural mechanism of hearing, and speakers will include Drs. Moses H. Lurie and Hallowell Davis, Boston; Albert C. Furstenberg, Ann Arbor, Mich.; Samuel T. Orton, New York; Douglas MacFarlan, Philadelphia; Hermon Marshall Taylor, Jacksonville, Fla., and Samuel J. Kopetzky, New York. Dr. Edmund P. Fowler, New York, will deliver his presidential address Thursday afternoon on "The Diagnosis of Diseases of the Neural Mechanism of Hearing by the Aid of Sounds Well Above Threshold." Friday afternoon the speakers will include Dr. Lee W. Dean, Dr. John S. Agar and Lloyd D. Linton, B.S., St. Louis, on "The Effect of Allergic Conditions on the Ear," and Dr. Page Northington, New York, "The Induced Nystagmus After Peripheral Vestibular Lesions in Monkeys."

American Board of Surgery Organized.—In answer to the widespread demand for an agency that will attempt to certify competent surgeons, the American Board of Surgery has recently been organized. This board is a member of the Advisory Board of Medical Specialties, which includes all the boards of certification for the different medical specialties that have been already organized. Since boards were in existence for the certification of practitioners of some of the surgical specialties such as ophthalmology, otolaryngology, obstetrics and gynecology, genito-urinary surgery and orthopedic surgery it is expected that the American Board of Surgery will be responsible for the certification of general surgeons as well as those practicing in the remaining specialized subdivisions of surgery.

Acting on the invitation of the American Surgical Association, the following surgical societies cooperated in the creation of the American Board of Surgery: the American Surgical Association, the Section on Surgery, General and Abdominal, of the American Medical Association, the American College of Surgeons, the Southern Surgical Association, the Western Surgical Association, the Pacific Coast Surgical Association and the New England Surgical Society. The first three of these bodies, which are national in scope, have three representatives on the board. All the other societies have one representative each. The representatives of the cooperating societies are nominated by the society which they represent and on approval of the board shall become members of it. The term of membership on the board will be six years. The following were chosen to represent the cooperating surgical societies:

Dr. Evarts A. Graham, Dr. Arthur W. Elting and Dr. Allen O. Whipple, representing the American Surgical Association.
Dr. Donald Guthrie, Dr. Edwin R. Schmidt and Dr. Harvey B. Stone, representing the American College of Surgeons.
Dr. Fred W. Rankin, Dr. Howard M. Clute and Dr. J. Stewart Rodman, representing the Section on Surgery, General and Abdominal, of the American Medical Association.
Dr. Philemon E. Truesdale, representing the New England Surgical Society.
Dr. Thomas Orr, representing the Western Surgical Association.
Dr. Robert Payne, representing the Southern Surgical Association.
Dr. Thomas Joyce, representing the Pacific Coast Surgical Association.
The following officers were elected: chairman, Dr. Evarts A. Graham; vice chairman, Dr. Allen O. Whipple; secretary-treasurer, Dr. J. Stewart Rodman.

Two groups of candidates are recognized for qualification by the board: (a) those who have already amply demonstrated their fitness as trained specialists in surgery, and (b) those who, having met the general and special requirements exacted by the board, successfully pass its qualifying examination.

The first of these groups, the Founders Group, on invitation by the board will be chosen from (1) professors and associate professors of surgery in approved medical schools in the United States and Canada, (2) those who for fifteen years prior to the board's organization have limited their practice to surgery, and (3) members of the American Surgical Association, the Southern Surgical Association, the Western Surgical Association, the Pacific Coast Surgical Association and the New England Surgical Society, who were in good standing Jan. 9, 1937.

All applications for the Founders Group must be received within two years of the board's organization, Jan. 9, 1937. No candidates will be considered after that date.

Requirements for those to be qualified by examination will be: 1. Graduation from a medical school of the United States or Canada recognized by the Council on Medical Education and Hospitals of the American Medical Association or graduation from an approved foreign school. 2. Completion of an internship of not less than one year in a hospital approved by the same council, or its equivalent in the opinion of the board. 3. Special training: A further period of graduate work of not less than three years devoted to surgery taken in a recognized graduate school of medicine or in a hospital or under the sponsorship accredited by the American Board of Surgery for the training of surgeons. This period of special training shall be of such character that the relation of the basic sciences of anatomy, physiology, pathology, bacteriology and biochemistry is emphasized. Knowledge of these sciences as applied to clinical surgery will be required in the examination. Adequate operative experience in which the candidate has assumed the whole responsibility will be required. An additional period of not less than two years of study or practice in surgery. 4. The candidate must present to the board sufficient evidence of good moral character as to justify it in the belief that he will not engage in fee splitting and other dishonest practices.

The qualifying examination will be divided into two parts: part I, written, and part II, clinical, bedside and practical. The written part, part I, will concern itself with general surgical problems and with the clinical application of the basic sciences of surgery to these problems. This examination will cover a period of three hours each and will be held simultaneously in as many centers as are necessary to accommodate the number of applicants who are eligible. Part II is entirely oral and will also concern itself, in the main, with general surgery and, as stated for part I, clinical application of the basic sciences to the clinical problem represented. In addition to this, in part II an examination will be given to test the candidate's knowledge of operative surgery, x-ray plate interpretation and the principles and application of surgical anesthesia. This examination will be held in as many centers as the board may determine necessary to accommodate the eligible candidates. Reexaminations will be allowed, provided one year shall elapse between examinations.

The fee for group A, the Founders Group, shall be \$25. The fee for group B shall be \$75, payable as follows: \$5 for registration fee, which shall be returned if the candidate is not accepted for examination; \$20 for part I, and \$50 for part II. The same fee will be required for each reexamination. Once the candidate has become qualified, he will have no further financial obligation to the board.

The board will hold its first examination (part I, written) Sept. 20, 1937. All inquiries concerning applications for this examination should be received by the secretary's office promptly.

Requests for booklets of information, application blanks and other information should be addressed to the secretary, Dr. J. Stewart Rodman, 225 South Fifteenth Street, Philadelphia.

CORRECTIONS

Births in Milwaukee General Hospital.—In the Hospital Number of THE JOURNAL, March 27, page 1118, the number of births in the Milwaukee General Hospital, Milwaukee, should have been reported as 431 instead of 43.

Bovine Tubercle Bacilli and Guinea-Pigs.—In the Paris letter in THE JOURNAL, February 27, page 739, it was said that the guinea-pig is not susceptible to the bovine type of tubercle bacillus. According to a standard textbook on bacteriology, guinea-pigs inoculated with the bovine type of tubercle bacillus die more quickly and show more extensive lesions than those infected with human bacilli. The bovine type is said to be more virulent for all the ordinary laboratory animals than is the human.

Government Services

SPECIAL ARTICLE

MEETINGS OF ADVISORY COMMITTEES ON MATERNAL AND CHILD WEL- FARE SERVICES UNDER THE SOCIAL SECURITY ACT

The General Advisory Committee on Maternal and Child Welfare Services under the Social Security Act met in Washington, April 7 and 8, to consider progress reports and problems concerning content of programs and policies with respect to the administration of title V of the act. Following an opening session at which Miss Lenroot, chief of the Children's Bureau, gave a short general report of progress, the members of the General Advisory Committee met with the members of four special committees on maternal and child health, services for crippled children, child welfare services, and participation by the public. In each of the special committees, progress reports were presented by the directors of the divisions administering the three parts of the act. Following a full discussion, recommendations were made by each committee to the General Advisory Committee. The reports and recommendations of the special committees can be summarized as follows:

ADVISORY COMMITTEE ON MATERNAL AND CHILD HEALTH

The Committee on Maternal and Child Health received and unanimously adopted recommendations made by the Subcommittee on Maternal Welfare with respect to an extension of the program under title V, part 1, of the Social Security Act and further recommended the submission of the report to the chief of the Children's Bureau for the purpose of taking the steps necessary for the accomplishment of the purposes outlined.

The recommendations of the Subcommittee on Maternal Welfare cover two special aspects of the program; namely, (1) increased and improved maternity care and care of the newborn and (2) a program of training in these fields for physicians and nurses. The recommendations are as follows:

1. Extension of the maternal and child health work begun in 1935 through federal cooperation with the states under the Social Security Act appears to be urgently needed. This requires appropriation of public funds for maternal care, medical and nursing, for all women in need of such care, considering need as including not alone economic but also medical needs and lack or inadequacy of existing facilities.

This extension should include not only provision of increased resources for actual maternal care, including care given locally by general practitioners and nurses, but also expert obstetric and pediatric consultation service in areas where such is not available and hospitalization of emergency and other selected cases. The establishment of such a program would involve adequate provision for three types of service:

- (a) Care in the home at delivery and during the antepartum and postpartum periods by a qualified physician aided by a public health nurse trained and experienced in maternal care.

- (b) Delivery care in approved or acceptable hospitals, provided with adequate obstetric and neonatal services and facilities equal to all emergency or complicated cases, for any woman who because of social, medical or economic reasons, or because of inaccessibility of skilled care should be cared for in a hospital.

- (c) Consultation service by obstetricians and pediatricians to aid general practitioners in their care of mothers and infants.

In the development of such an extended program, the right of the patient to select her own physician should be preserved.

2. It is the opinion of this committee that a center or centers of postgraduate education should be established to teach urban and rural practitioners of medicine and nurses the fundamental principles of complete maternal and infant care.

Having accepted the principle of providing short intramural courses in obstetrics and care of the new-born infant for general practitioners, the committee recommends:

- (a) That such training positions carry maintenance and necessary traveling expenses.

- (b) That intramural postgraduate instruction be a special assignment of members of the teaching staffs of medical schools.

3. The committee recognizes the necessity and desirability of cooperation with the national, state and local medical societies in the working out of any plan.

As reasons for the importance of these resolutions on the extension of maternity care and care of the new-born, the report of the Advisory Committee on Maternal and Child Health Services states:

The progress that has been made in the field of maternal and child health can be traced by the mortality rates. The maternal mortality rate has shown but little appreciable decline in this country. Whereas infant

mortality has been reduced almost one half during the first year of life, this reduction has occurred almost entirely after the first month. The mortality rates remain practically the same for the first week and for the first month of life.

Only by available and adequate care for the mother during the pregnancy cycle, especially at time of delivery, can the death rate for mother and child be lowered. It is therefore essential that, to bring any further reduction in maternal as well as infant death rates, further development of the program is necessary.

In addition, the Committee on Maternal and Child Health Services adopted the following resolutions for submission to the General Advisory Committee on Maternal and Child Welfare Services:

1. That a special committee be appointed to consider problems in the field of health education.

2. That it would be desirable to have a few complete demonstrations developing and applying available knowledge in the field of nutrition and to use these centers not only as demonstrations but also as areas where training in nutrition might be available to those interested. This should be a coordinated effort of educational, health, welfare and agricultural agencies.

3. That the Children's Bureau appoint an advisory committee on research problems in administration of maternal and child health programs.

In considering the work of the maternal and child health division of the Children's Bureau as reported by the director of the division, the Advisory Committee on Maternal and Child Health Services emphasized the desirability in future planning of having the state bear at least one half the administrative expense of the state maternal and child health program, in order to make an increased amount of federal funds available for local areas. Continued cooperation with the medical profession was endorsed and the importance of solving the problem of cooperation with professional and lay groups was stressed, especially in connection with several states where the success of the program appears to be jeopardized by failure to use the advisory committees.

The committee discussed at some length the importance of studies and investigations of various phases of the maternal and child health program, as, for instance, dental hygiene, nutrition, health education and mental hygiene.

ADVISORY COMMITTEE ON SERVICES FOR CRIPPLED CHILDREN

The meeting of the Committee on Services for Crippled Children, April 7, was the third one since the passage of the Social Security Act. Following the report by the director of the division, the committee was broken up into two groups to consider (1) problems of medical and hospital care and (2) state administrative procedures. The report of the committee as a whole may be summarized as follows:

The committee noted with satisfaction that every state and territory except one has designated an official agency.

The committee reaffirmed and amplified its previous recommendations concerning desirable qualifications of surgeons and other trained personnel to be employed by official agencies. The statement of qualifications and functions of physical therapy technicians prepared for the use of state agencies and approved by the Council on Medical Education and Hospitals of the American Medical Association and the American Physiotherapy Association was accepted as adequate. Reports of progress were given concerning the training of public health nurses and medical social workers to be employed in state programs. The committee reaffirmed its previously stated position regarding the desirability of a definite plan for the continuous education of the state staff as well as improving the qualifications of incompletely trained personnel already employed.

The preliminary studies by the staff of the Children's Bureau concerning fee schedules, hospital rates and other charges were examined by the committee and approved with suggestions as to future studies.

The registration of hospitals by the American Medical Association was recommended as an additional safeguard to desirable standards formerly proposed by this committee.

The committee urged that the Children's Bureau assist state agencies in reviewing the type of care given to individual children in hospitals and reaffirmed its recommendation of the desirability of a flat per diem ward rate exclusive of professional fees and charges for appliances.

The extension of convalescent facilities and after-care services in reducing the duration of hospital care was recommended, and reports were received with respect to standards for convalescent and foster-home care.

The committee reemphasized the need for the establishment and continuous maintenance of an adequate state register of crippled children.

The plan for the classification of crippling conditions to be used by the states was discussed and suggestions made with respect to forms for reporting. The plan proposed is based on the National Conference on Nomenclature of Diseases.

The importance of working agreements with other public and private agencies engaged in providing related services to crippled children in the attainment of satisfactory adjustments leading to social and economic self maintenance was recognized.

The use of state advisory committees as interpretative groups serving the state agency and the community was urged. The use of small sub-

committees serving as advisory groups on technical problems was also recommended.

The committee made additional suggestions for future studies to be conducted by the Children's Bureau, which it was hoped would lead to improvement of services.

In closing, the committee expressed its confidence in the methods of administration used and the policies which have been developed by the Children's Bureau in its services for crippled children.

ADVISORY COMMITTEE ON COMMUNITY CHILD WELFARE SERVICES

The Committee on Community Child Welfare Services met with the staff of the Child Welfare Division of the Children's Bureau on April 7 to hear reports of progress in development of state services for the encouragement and assistance of adequate methods of community welfare organization in areas predominantly rural and other areas of special need and in the development of actual child welfare service programs in such areas.

Representatives of professional and lay groups in the various states have assisted in the development of the initial stages of the child welfare service program. During the next period there is continuing need for such participation. One method is through the use of state and local committees.

The consensus among the members of the advisory committee with regard to the development of such committees was as follows:

1. An informed interest on the part of citizens is essential to insure the development and maintenance of the public program.
2. The methods by which administrators can best reach the public will vary from state to state and from community to community, and may be through formally organized committees or through more informal channels.
3. State committees may be of two kinds:
 - (a) An informal group of technical advisers on whom the administrator calls for advice concerning the professional aspects of the program. This group may be small or large and is not limited as to term of service.
 - (b) A state citizens' committee for the purpose of interpretation and support. Such a committee may not be formally appointed by the department concerned, although its development may be indirectly stimulated by the department.
4. In local areas it is the primary responsibility of the child welfare worker to develop community organization and interest along with technical child welfare services to individual clients. Local groups should be interested in the program on the basis of specific services which they may perform in connection with it. As an outgrowth of interest in such service, certain citizens may be chosen to serve as members of a more formal committee, if that seems desirable.

The Advisory Committee also heard reports of a special committee on training and personnel, which is working with both the Children's Bureau and the Public Assistance Division of the Social Security Board.

SUBCOMMITTEE ON PARTICIPATION OF THE PUBLIC

A subcommittee, which included the members of the General Advisory Committee on Maternal and Child Welfare Services representing citizens' organizations, discussed many problems in the maternal and child welfare programs under the Social Security Act. In its report to the General Advisory Committee, the subcommittee recognized that the program for maternal and child welfare services is dependent on increasing understanding on the part of the public so that adequate support may be given, quality of service maintained and activities extended to reach new groups and new areas. The committee asked the Children's Bureau to make available to the state administrative agencies suggestions as to the composition, use and functions of advisory committees. It was the sense of the committee that, in the appointment of working advisory committees in the states, organizations be selected for representation because of their special activity in the particular field and that all organizations concerned with the various programs be called in conference from time to time by the state agencies concerned. The committee suggested that the various state organizations request the state agencies to issue at stated intervals brief summaries of activities for their use in informing their members of the progress that is being made in the maternal and child welfare programs.

The recommendations of these four special committees were received and endorsed by the General Advisory Committee at its meeting, April 8. The recommendation with respect to the extension of the maternal and child health program under title V, part 1, of the act to include resources for increased and improved maternity care and care of the new-born and a program of training for physicians and nurses was given special consideration and unanimously adopted by the committee.

RECOMMENDATIONS OF THE CONFERENCE OF STATE AND TERRITORIAL HEALTH OFFICERS

The Conference of State and Territorial Health Officers, meeting with the Children's Bureau April 9, unanimously adopted the following report of a joint meeting of the Committee on Maternal and Child Health of the State and Territorial Health Officers and the Child Hygiene Committee of the State and Provincial Health Authorities of North America:

The conference, at its last annual meeting, adopted the committee's recommendations relating to a revised plan for development of maternal and child health programs, local programs, health services, state-wide program, and federal participation with states.

At a joint meeting April 4 the committees considered other timely and necessary steps in our programs of maternal and child health activities and the following recommendations were unanimously adopted:

1. That the Children's Bureau prepare and send a questionnaire relating to present facilities and resources for maternal and child health to the states and territories.
2. That the medical schools of the country be encouraged to provide more adequate instruction in maternal and child care through their obstetric and pediatric departments in order that their graduates may be better prepared to practice preventive as well as curative medicine and render service of such a character that the maternal death rate would be lowered and that further reduction would be made in the infant death rate, and that the assistance and cooperation of the Council on Medical Education and Hospitals of the American Medical Association be enlisted in the furtherance and promotion of this program of better instruction in these schools.
3. That it is necessary to extend the maternal and child health work now being conducted in the states and territories. For the purposes of developing sound procedures in this field, the joint committee recommends that (1) resources be made available so that qualified local practitioners of medicine and qualified nurses be made available for all aspects of maternal care to those women who are unable to secure this service otherwise, and (2) necessary consultation service and emergency hospitalization for these women should also be provided.
- Medical leadership is both desirable and necessary, and the right of the patient to choose her own physician should be recognized.
4. That the facilities for postgraduate education for physicians and nurses be extended and that in cooperation with the state medical societies an analysis be made of the causes of maternal deaths in order to demonstrate the need for better obstetric practice.

A report on the progress of the crippled children's program was presented to the Conference of State and Territorial Health Officers by the director of the crippled children's division of the Children's Bureau. The previous recommendations of the State and Territorial Health Officers with regard to services for crippled children were reviewed and the Children's Bureau was requested to prepare a registration card for the optional use of states to aid in developing a uniform system of registration for crippled children.

The members of the Child Hygiene Committee are Drs. Felix J. Underwood, Mississippi, chairman; T. F. Abercrombie, Georgia; P. H. Bartholomew, Nebraska; T. P. Burroughs, New Hampshire; P. S. Campbell, Nova Scotia; G. H. Coombs, Maine; J. D. Dunshee, Idaho; W. B. Grayson, Arkansas; V. K. Harvey, Indiana; Bernard T. McGhie, Ontario; E. G. Morales, Puerto Rico; F. E. Trotter, Hawaii, and Maysil M. Williams, North Dakota.

The members of the Committee on Maternal and Child Health are Drs. Felix J. Underwood, Mississippi, chairman; T. F. Abercrombie, Georgia; Earle G. Brown, Kansas; Henry D. Chadwick, Massachusetts; E. R. Coffey, Washington; J. Rosslyn Earp, New Mexico; R. C. Cleere, Colorado; V. K. Harvey, Indiana, and R. H. Riley, Maryland.

Health in Civilian Conservation Corps

The health of the Civilian Conservation Corps was satisfactory during the past year, according to the annual report of the surgeon general of the U. S. Army for the calendar year 1935 and the fiscal year ended June 30, 1936. The admission rate is higher than that of the regular army, but this is to be expected because of the youth and inexperience of the enrollees, their susceptibility to measles and mumps and the nature of the work in which they are engaged. The mean strength of the corps was about 394,000. There were but 102 cases of typhoid during the calendar year and many of these persons were probably infected before enrolment. There were 360 cases of tuberculosis. By means of the rapid x-ray examination of the chests of applicants for enrolment, recently inaugurated by the army, a rate of 7 per thousand in white men under 30 years of age and 8 per thousand in Negroes was recorded among a group of 7,000 men examined.

The Nutrition of the Nation

In 1935 the minister of health appointed a committee to investigate the diet of the people and to report on any changes that appear desirable in the light of modern advances in the knowledge of nutrition. The committee has now published a report in which it states that this is "the first occasion in history that a comprehensive survey, statistical and physiologic, of the diet of a whole nation has been set on foot by any government." It regards the consumption of a sufficient quantity of milk as the key to proper nutrition. The desirable amount for children is from 1 to 2 pints daily, for expectant or nursing mothers about 2 pints, and for adults about half a pint. Our present national consumption of milk is not half what would correspond to these amounts. "No other single measure would do more to improve the health, development and resistance to disease of the rising generation than a largely increased consumption of safe milk, especially by mothers, children and adolescents." The committee says that recent advances in the science of nutrition have shown that improvements in health and physique can be attained by consumption of adequate amounts of the protective foods. The progressive application of this knowledge has already contributed to general improvement in health and to decline in mortality and in the incidence of deficiency diseases, such as rickets. The greater availability of butter, cheese and fruit and the increased attention given to the nutrition of mothers and children have also played a part. But there is much room for further improvement.

The national diet contains sufficient energy-giving foods for the whole population, and all except a small fraction of the population is obtaining the full amount of calories it requires. It has been computed that the national food supply per annum contains 55,700 thousand million calories, or, allowing for a wastage of 10 per cent, 50,100 thousand million calories, as compared with the estimated net requirements for the population of 44,300 thousand million calories on the basis of the report of the League of Nations Health Organization. The consumption of fat has largely increased in recent years, which suggests that there is no aggregate deficiency, though there may be some deficiency in the diet of the poorest. No shortage of protein has been revealed, but not all protein is of the same nutritional value; the consumption of protein of high nutritional value (meat, fish and dairy products) rises with income. It seems that the national consumption of fruit and vegetables is below the requirements for optimal nutrition. The committee agrees with the technical commission of the League of Nations that sea fish is particularly valuable as a source of good protein, of iodine and other minerals, that herring and mackerel are particularly rich in vitamins A and D, and that the consumption of potatoes (now about 56 ounces a head weekly) should be increased so as to replace some of the sugar and highly milled cereals in ordinary diets.

It is proposed to investigate further the distribution of the national income by income groups, family budget material, and quantitative dietary studies.

Rules for Resident Medical Officers of Hospitals

The British Medical Association has issued a statement of the principles that should guide hospitals in the employment of junior resident medical officers.

1. The junior resident medical officers should devote their whole time to the service of the hospital. 2. Their duties should

include the admission and discharge of patients in accordance with the wishes of the responsible medical officer in charge of the case. 3. They may be required to give lectures to nurses or to examine and treat nurses, and in serious cases they should report to the responsible medical officer. 4. They should as soon as possible notify him of the admission of urgent and important cases and of any serious change in the condition of any case. 5. They should not permit any patient, prescription paper or notes to be examined by any one without the sanction of the responsible medical officer and should not furnish any one unconnected with a patient with any information respecting the case without the sanction of the responsible medical officer and the consent of the patient. 6. They should have definitely prescribed periods off duty; for example, two half days a week after 2 p. m. and alternate Saturdays after 11 a. m. They should have a two weeks holiday for every six months of completed service. 7. The responsibility for giving certificates and medical reports and their entitlement or nonentitlement to retain fees for them should be clearly defined in the hospital rules.

Cooperation Between Medical Schools and Psychotherapists Desirable

In a communication to the *Times*, Sir Walter Langdon-Brown, emeritus professor of physic in the University of Cambridge, supports a suggestion advocating closer cooperation between the medical schools and psychotherapists, which he has been advocating for several years. He points out that the ordinary medical student receives more instruction in certifiable mental disease than in the earlier and more amenable forms of such troubles. Such teaching has had from force of circumstances to be confined to outpatient clinics held by psychiatrists, who must feel that their opportunities are restricted and inadequate. Yet as a member of three separate bodies concerned with the revision of the medical curriculum Sir Walter can testify that the urgent need for greater opportunities is freely recognized. He holds that it is of the first importance that from the beginning of his clinical work every medical student should recognize not only the symptoms of "nervous breakdown" but the fact that every illness has its psychologic side. This can be brought about only by the psychiatric department forming an integral part of the general hospital. There can be no doubt as to the benefits such a scheme would bring to national health and happiness.

Charles Coley Choyce

Prof. Charles Coley Choyce, the editor of the well known *System of Surgery*, who had recently retired from the post of director of the surgical professorial unit of University College Hospital, London, has died at the age of 61 years. Born in Auckland, New Zealand, he graduated B.Sc. in the university of that country and then went to the University of Edinburgh, where he graduated M.B., Ch.B., in 1901. In 1905 he obtained the F.R.C.S. of England and settled in London, where after holding various junior surgical appointments he was elected surgeon to the Seamen's and Great Northern hospitals. He soon established a reputation as a teacher of surgery and in 1911 produced his *System of Surgery* in three volumes, which was an immediate success. He had all the qualities for such an undertaking—a sound knowledge of surgery, great teaching ability, a good command of English and tact for the management of a corps of eminent contributors. On the outbreak of the war he joined the army and for nearly two years was in charge of the surgical division of the Nineteenth General Hospital. In 1917-1918 he was consulting surgeon to the Egyptian Expeditionary Force with the rank of colonel. After the armistice he was appointed director of the newly formed surgical unit at University College Hospital and professor of surgery in the University of London.

Diagnosis and Treatment of Cerebral Injuries

At the March 3 meeting of the Académie de chirurgie Dr. Clovis Vincent read a paper on the diagnosis and treatment of cerebral injuries. Dr. Vincent, up to about ten years ago, was one of the leading neurologists in Paris. Since that time he has devoted himself to neurosurgery. His idea was to study the effects of cerebral injury in noting the clinical course following operations for cerebral tumors. By observing from hour to hour the postoperative course, one learns to know when unfavorable symptoms appear. Some patients were reoperated on and thus it was possible to study in the living a number of lesions that may cause death. The most frequent of these are extradural hematoma, serous meningitis, acute ventricular effusion and brain collapse. These conditions may occur singly or associated, with predominance of one lesion. Among the phenomena that surgeons observe as a postoperative complication, three are to be especially borne in mind: cerebral edema, arterial hypertension with cerebral vasodilatation, and acute pulmonary edema. Lesions of the brain stem are much more likely to end fatally than those of the cerebral hemispheres. A mechanism is present, according to Vincent, in the wall of the third ventricle the stimulation or paralysis of which is followed by cerebral edema, especially of the frontal lobe. A clinical observation was cited to confirm this opinion.

There exists in the bulb near the nucleus of origin of the tenth pair of cranial nerves a mechanism that appears, when traumatized, to give rise to generalized hypertension, intense cerebral vasodilatation and acute pulmonary edema. This observation was made by Vincent in operating on the posterior fossa of the skull in several cases of tumor of the cerebellum.

Vomiting, polyuria with polydipsia and often glycosuria as well as a more or less deep sleep were observed in operating near the third ventricle. Patients do not die as the result alone of injury to the centers that govern life directly but also from the dysfunction of various mechanisms which control the systemic as well as interstitial circulation of the brain, which in turn regulates the secretion of the cerebrospinal fluid, consciousness and also the functions of the liver, pancreas and adrenals.

Vincent does not believe that any difference exists between changes due to operative interventions and those following ordinary trauma to the skull and brain. Hence the treatment of the latter, so far as the cranial contents are concerned, can be deduced from observations made in cases in which operations have been performed for nontraumatic lesions, such as tumors, as follows: If the patient is conscious and there are no localizing symptoms, nothing should be done except to put the patient to bed and watch closely, as no one can foretell when serious symptoms may appear. If the patient is comatose when first seen, the gravity of the symptoms, the time elapsed since the accident and the sequence of appearance of the symptoms must be the deciding factors. If the injury is a recent one and the general condition indicates such serious damage to vital nerve centers that the patient can live but a few days, it is advisable to do nothing. If the injury is a recent one and the patient is in a serious condition but there is a history of a free interval without any symptoms, absolute or relative, operation is indicated. If the patient is comatose but the essential vital functions are normal or nearly so, there is no immediate danger and one can wait, meanwhile watching for any symptoms that might call for operative intervention. Such surveillance includes the constant presence of a nurse at the bedside to note, from hour to hour, the pulse, respiration and temperature. Any changes in the ability of the patient to swallow are especially to be noted, as well as loss of con-

sciousness, convulsions, paralysis and urinary incontinence. The attending surgeon himself ought to see the patient at least every six hours. If convulsions of the jacksonian type, followed by a rapidly progressive hemiplegia, appear, these are definite indications for operation. Such symptoms are but rarely observed, so that the more important question is the degree of involvement of the vital centers.

Following a review of the different types of consciousness, Vincent stated that it is the degree of automatic and instinctive consciousness, as well as the manner in which the patient acts during the second stage of deglutition, which enables the surgeon to judge the condition. The respiration can be changed both in quality and in rhythm. The progressive slowing of the pulse rate, as shown on a relatively long curve on the chart, is of much importance. An isolated rise of temperature is of less value than a steadily increasing rise. Unilateral dilatation of the pupil does not necessarily indicate the side on which a hematoma is located. One of the best signs of compression is papillary stasis. Much importance should be attached to the gradual appearance of mental confusion ending in coma. Cerebral edema, developing slowly, also gives rise to progressive inability to swallow, as well as to disturbances of respiration and pulse rate. Cerebral edema is the most common complication of skull fractures. It can be responsible for the coma, even when there is no hemorrhage, but it frequently accompanies these. It can appear so acutely as to cause death within the first twenty-four hours. Usually it appears slowly, preceded by a lucid interval, as in cases of subdural or extradural hematoma.

Owing to the difficulty of diagnosis in certain cases, the author endorsed the suggestion of Petit-Dutaillis, of ventricular puncture during exploration. The information yielded by lumbar puncture is far inferior to that following the use of the Petit-Dutaillis method. In conjunction with the latter, Vincent advises the use of four trephine openings (two frontal and two temporal), which permits obtaining a larger field for inspection of the brain and its coverings as to the presence of hematomas.

TREATMENT OF SKULL INJURIES

Lumbar puncture and intravenous injections of hypotonic or hypertonic solutions are too frequently given without definite indications having been established. In head injuries, lumbar puncture may be a good method of treatment for slight extra-arachnoid meningeal hemorrhages predominantly located at the base of the brain. It is indicated also in diffuse serous meningitis if one is sure that it exists. But lumbar puncture cannot be regarded as a treatment of hematoma, of encysted serous meningitis or of cerebral collapse. Lumbar puncture cannot be considered as adequate when employed alone in edema of the brain. Following an operation for head injuries, Vincent frequently employs hypertonic or hypotonic solutions intravenously. The former are particularly useful after operation for traumatic edema of the brain.

TREATMENT OF HEMATOMAS

A hematoma large enough to give rise to signs of compression ought to be evacuated. Whether its location is extra-cerebral, subcerebral or intracerebral, a large opening should be made in the skull under local anesthesia. Rupture of a branch of the middle meningeal artery is less frequently the source of a hematoma than is generally taught. A fissured fracture can give rise to as much bleeding. After removal of the clot, preferably by aspiration, the dura is exposed, but a thin layer of coagulated blood is left on the brain. All visible intracranial bleeding is controlled by electrocoagulation, that from the bone edges by wax. Vincent never drains, having found that bleeding recurs as often with as without drainage. If a subdural hematoma is found, the opening should embrace a wide area of the vault of the skull; viz., a part of the frontal,

occipital and temporal regions and all of the parietal. To avoid extending the bone flap too far downward, an incision is made through the lowest point of the exposed dura to see whether the hematoma is continuous with one at the base. The latter constitutes a serious complication and death may occur during the operation. If the hematoma on the exposed surface is of greater duration, from two to three months for example, only the contents of the cyst that has been formed need be evacuated. To avoid secondary hemorrhage, the lateral ventricles, after every operation immediately following injury, should be filled with Ringer's solution. Intracerebral hematomas can be best evacuated by aspiration.

TREATMENT OF CEREBRAL EDEMA OF TRAUMATIC ORIGIN

If the edema involves the hemispheres, the best site for opening the skull is in the right frontal region, extending 4 or 5 cm. to the left beyond the median line. Subtemporal decompression alone is of no help in these cases. The edematous brain must be allowed to expand toward the vault so as to relieve the pressure on the vital structures at the base of the brain. The operation is completed by a subtemporal trephine opening with incision of the dura at its lowest point if there appears much subdural tension. The pedicle for the frontal osteoplastic flap should be in the temporal region. A large opening in the skull decompresses better than one realizes even without incision of the dura. In addition to such a wide frontal decompression procedure, Vincent advises intravenous injections of 15 per cent magnesium sulfate, 4 cc. every three to four hours, and a minimum of 12 mg. of strychnine sulfate in twenty-four hours.

TREATMENT OF COLLAPSE OF THE VENTRICLES

When recognized, Ringer's solution at a temperature of 37 C. (98.4 F.) is injected during operation directly into the lateral ventricles, through a small trocar with blunt ends. One must be sure that no cerebral edema exists; if such is the case, death may ensue immediately after injection of the ventricles.

Transmission to Ferrets of Human Influenza Virus

Reference has already been made to a report by de la Rivière and Cheve, at the Nov. 24, 1936, meeting of the Académie de médecine, showing that ferrets could be infected either with rhinopharyngeal mucus of human beings suffering from influenza or from ferrets previously inoculated. At a recent (February 9) meeting of the same society these investigators reported the results of further experiments. The material for inoculation of ferrets was obtained on the second or third day of an attack of acute influenza. The patients were asked to gargle with 50 cc. of a mixture composed of equal parts of physiologic solution of sodium chloride and bouillon. One half of this solution was used to determine the ordinary flora of the pharyngeal secretions of the patients and the other was filtered (Chamberland L 2). The sterility of the filtrate was controlled by inoculation on various aerobic and anaerobic mediums. No colonies appeared even after a week's incubation. The filtrate was then instilled intranasally in the ferrets and their morning and evening temperatures were recorded. A healthy animal was thus inoculated with the nasal secretion (diluted one fifth to one tenth in physiologic solution of sodium chloride and passed through an L 2 Chamberland filter). Some inoculations were also made by instilling into the nares of a healthy animal a 5 per cent suspension of the pulverized lung of an infected ferret. In both of these types of experiment a typical infection resulted. Throughout their study they found that the inoculation of the filtrate of the rhinopharyngeal secretions from cases of human influenza gave rise to identical manifestations, as had been found in employing a virus obtained from England derived from passage of the virus through mice. The temperature curves of human beings suffering from influ-

enza and inoculated ferrets were identical. A ferret inoculated a month previously with a virus obtained in London, when reinoculated with a filtrate from a recently infected human being, did not present evidences of the disease. A healthy ferret, however, was successfully inoculated with the same London virus, showing that the animal which had been reinoculated was immune.

Treatment of Fractures of the Skull in Children

At the March 3 meeting of the Académie de chirurgie, Clovis Vincent reviewed the symptoms and indications for operative intervention in brain injuries complicating skull fractures in adults. At the following meeting the experience acquired in observing 109 cases of skull fracture in children was the subject of a paper by the Sorrels and Gigon. A neurologic examination in every case had been made by André Thomas. The children varied in age from 3 months to 15 years, the majority of fractures following injuries on the street. Neither the extent of the line of fracture nor the number of its radiations seemed to bear any relation to the gravity of the clinical symptoms. All the classic meningo-encephalitic complications had been observed. The increase in pulse rate is an unfavorable sign, from the standpoint of prognosis. Among the neurologic signs two are of major importance: diminution of muscle tonus and a diminution in the rapidity with which an extremity falls when lifted. Pupillary changes are too inconstant to be of much value. Aside from cases in which operation is imperative (open fracture and intracranial hematoma) and those in which one does not hesitate to operate, there were others in which the question of whether or not to operate was much more difficult to decide. During the first thirty-six to forty-eight hours, if the coma persists and the pulse remains rapid, operation is indicated without delay, even after a temporary apparent improvement, if signs of involvement of nerve centers, mental confusion and a rapidly increasing pulse persist. Fractures of the skull in children are relatively benign, even though serious symptoms are present at the onset. These fractures heal with surprising rapidity, many within one to two weeks. Sequelae are comparatively infrequent (in only 3.5 per cent of the cases) in children. If an operation is performed early, important nerve sequelae are rarely observed.

News of the Student Bodies

Since the last report on the faculties and student bodies of German universities (*THE JOURNAL*, July 4, 1936, p. 50) some further developments have taken place. It is eloquent of the situation that National Minister of Public Instruction Rust recently saw fit to address a public admonition to the university students. Rust declared in his speech that it is not the business of the students to "subject the docents (their own teachers!) to a thorough microscopic examination" for the purpose of "getting rid of them." Every student should make demands, not of others, but of himself. Rust expected not phraseology but accomplishment. In view of present conditions the minister must impose large obligations on students as well as on the research and teaching staffs of the universities.

It is perhaps significant that the whilom fuchrer of the Nazi German Students' League, Derichsweiler, has been deposed. The removal of this quarrelsome bully followed the demands of a vast number of professors who found their scholarly activities cruelly handicapped by the constant feeling of unrest. Two student organizations, the German Studentenschaft and the Nazi Studentenbund, are now united under the common headship of a "National Fuchrer of Students."

Henceforth all new matriculants at a university must register at the headquarters of the local student fuchrer. During the

first three semesters of residence a student will receive "politisch-weltanschaulich" instruction from the Nazi Studentenbund. To facilitate this program of indoctrination it has been decreed that a student must spend the first three semesters at one university. Heretofore a student has been free to transfer from one school to another at the end of any semester, and this flexibility has been a peculiar characteristic of German university life. Every German student shall have the opportunity of joining one of the "kameradschaften" sponsored by the Nazi Studentenbund. Far reaching and explicit regulations govern the conduct of these student organizations. Certain members of the Nazi Studentenbund, such as the Stamm-Mannschaften and the office holders are permitted to wear a distinctive uniform: a black coat under which is worn the brown shirt. A special flag has also been designed. The director of the Culture Bureau of National Student Activities has declared that a new type of campus life should be developed. The new National Socialist university milieu will have to evolve gradually. Planned "sings" and other musical activities, and carefully arranged social evenings may perhaps eventually come to take the place of the old student "kommerse" (the drinking bouts that were a famous feature of German student life). A new students' code of honor has also been created, based on the absolute satisfaction of affronts by the duel. This code, still in process of being drafted, regulates dueling and the use of weapons, with particular reference to saber duels. Affairs of honor will be decided by the saber duel. Since drunkenness is considered unworthy of a German, a student who receives an affront while he is intoxicated has no right to demand satisfaction. If a German student, while under the influence of drink, should offend the honor of a fellow student, the incident must be settled otherwise than by dueling. It will be recollected that after the war the German government prohibited dueling among students. The custom, however, continued to have a desultory clandestine existence and occasionally duelists were actually punished. But in the years just prior to the advent of the present régime the enforcement of the laws against dueling had been extremely lax.

All future students who have completed secondary school and intend to enter a university must first put in a year of labor service. Students unfit for labor service proper must spend the same period in some prescribed equivalent service. Labor service is now compulsory for all the youth of Germany. Exceptions are, however, granted in special cases, especially for youths who contemplate certain technical studies such as aeronautics, ship building, marine engineering and marine electrotechnics. Exemption from labor service is granted in these cases in order to save time, as there is a marked shortage of young technicians in the mentioned fields.

Women who contemplate a university career must also put in a year of labor service. Those who are unfit may perform special duties in the Nazi Social Welfare Service. According to the terms of an agreement between the National Student Administration and the German Red Cross, women medical students must include in their course of study special training for emergency medical service in case of aerial attack. In the first semester the women are trained in the fundamentals of first aid service, in the second semester and during vacations they are trained as Red Cross "Samaritans," and from the third to the seventh semesters they spend their vacations in training as Red Cross assistants. The latter type of training includes three months in a hospital service. After the preliminary examination taken at the end of the fifth semester, the woman medical student is placed on the reserve list for emergency service in case of aerial attack. It is now prescribed by law that a woman student who appears for the state examination in medicine must be certified to have fulfilled the requirements with regard to "medical service in case of aerial attack."

Observations of Divers

Professor Ferdinand Wiethold of Kiel has investigated the changes produced in divers by a too rapid descent into the water. These may be of a dangerous character if they result from lack of air in the diving dress or a careless manipulation of the helmet valves. The increased water pressure decreases the volume of compressible air to such a degree that soon the helmet alone contains air, while the pliable texture of the dress proper permits the garment to become tightened about the entire body by the full force of the hydraulic pressure, which increases according to depth. Any further increase in the water pressure then causes that part of the body which is enveloped in the pliable dress to be under greater pressure than the helmet-protected head, neck and shoulders, the latter parts being subjected to the lesser pressure of the air content. From this state of affairs results (1) mechanical hindering of the respiration, (2) shifting of the blood from those parts of the body which are under unchecked water pressure to those parts which are under lighter pressure due to the protection of the helmet (pressure stasis) and (3) effect of aspiration on the respiratory passages and the lungs.

The pressure stasis and the mechanical hindrance to respiratory movement become dangerous only if present for a long time. The cupping glass effect on the lungs appears to be the most serious factor, as this quickly leads to a hemorrhagic pulmonary edema or even to total hemorrhagic infarction of the lungs. For divers who descend to great depths not at the beginning of submersion but after having breathed the compressed air at a higher level for some time, there is greater danger since the pulmonary alveoli, filled as they are with bloody moisture, lose their ability to eliminate the gases produced. In this way too there arises the danger of decompression injury. The foregoing observations are based on actual clinical and postmortem study of deep sea divers as well as on animal experimentation.

Progress with Asocial Venereal Disease Patients

In central Germany (Thuringia) a detention unit for asocial female patients afflicted with venereal diseases was created by the ministry after the way had been prepared by appropriate legislation. Data based on the eighteen months existence of this department are now available. Duration of internment depends on former behavior, the number of infections suffered, the previous expenses, the home surroundings and the social prognosis; the last named is determined by an attending psychiatrist. The behavior of these asocial persons during internment is also taken into consideration. The patients are treated until cured at the dermatologic clinic of the University of Jena. If a patient exhibits no further clinical manifestations, she is subjected to rigorous work therapy. When a youthful patient is released, an effort is made to reunite her with her family. For older patients and those without family, a placement bureau finds employment. If a job is found for a former patient, it must not be relinquished and a follow up is maintained by social welfare agencies. According to the data, some of the asocial women for whom employment was found relapsed into loose conduct. Against such persons rigorous measures, notably prolonged detention, were instituted. The method followed by this unit has shown itself to be well worth while and its wider application is to be recommended.

Better Food for Young Workers

The National Ministry of Labor has issued regulations which seek to guarantee suitable nourishment during working hours for growing youths employed in industry. The concentration of the working hours into the strictest possible limits with only brief pauses, a situation that has become increasingly prevalent in the cities, makes it generally impossible for the young worker to take his midday meal at home. Although some employers

are accustomed to provide their employees with warm, nourishing and inexpensive meals, this is by no means a universal custom. The new regulations provide that all industries, the lesser as well as the greater, must furnish at least a bowl of hot soup to the youthful worker during the noon recess. It is pointed out that this plan will be of benefit to the employer as well as the employee, since the better nourished worker will do better work. The inspectors from the Industrial Supervision Authority will see to it that the new regulations are observed, especially with respect to the furnishing of soup or other warm food to workers under the age of 18.

BUCHAREST

March 25, 1937.

Atypical Forms of Neurosyphilis

At a recent meeting of the medical society, Professor Paulian stated that syphilis, when localized, may produce symptoms simulating those of lethargic encephalitis. The symptoms of epidemic encephalitis, accompanied by the diagnostic signs of neurosyphilis may often be recognized. Of these, anisocoric pupils and the Argyll Robertson sign take first rank. These two manifestations, however, are constant in only three fourths of the cases and neither is pathognomonic. Thus absolute diagnosis cannot be made on symptoms alone, but the complete examination of the spinal fluid is imperative.

The pathologic picture described by Claude and Lhermitte under the syndrome of the infundibulum may be caused not only by syphilis but also by encephalitis or neoplasms. Another interesting localization is the dysphagic form of neurosyphilis, described by Professor Bacaloglu of Bucharest University. In cases of this nature the patient has to be fed with a tube and cannot swallow solid or liquid foods. Specific infections of the small brain may mimic tumors so much that these patients are subjected to operation. So-called essential epilepsy may be estimated to be of heredosyphilitic nature in about 16 per cent.

The evolution of the clinical manifestations of neurosyphilis requires from six to fifteen years. In this way there exists a latent period, which is revealed only by the analysis of the spinal fluid. Lumbar puncture should be made in every case of syphilitic infection. By doing so, efficacious prophylactic measures against the outbreak of neurosyphilis may be taken. If the spinal fluid is tested only when the presence of neurosyphilis is suspected, the advantages of the treatment during the latent and preclinical stages are missed.

According to a law recently passed by the national assembly and the senate, the military service required of young physicians has been extended to twelve months. This period was formerly of two months' duration. Of the twelve months the first two is devoted to military training. The next eight months service is placed at the disposal of the minister of health, during which time the young physicians are assigned to medical service in villages. The remainder of the time is again devoted to the army during the grand maneuvers. In this way the minister of public health hopes to improve the medical service in the villages.

Scarlet Fever Peritonitis

Dr. Gavrilă, lecturer to the University of Bucharest, describes three cases of scarlet fever in which primary, acute, purulent, generalized streptococcal peritonitis occurred. The first patient, a girl aged 13, had a mild scarlatina, and on the twenty-second day, during normal convalescence, a purulent peritonitis set in. Immediate surgical intervention failed to save her life. The second patient, a boy aged 12, had acute peritonitis on the twenty-fourth day of a severe septic scarlet fever. Surgical intervention here also was ineffective. The third patient had purulent peritonitis on the eleventh day of septic scarlet fever.

The patient died without surgical intervention. In all three cases hemolytic streptococci could be cultivated from the abdominal pus. Internal treatment is usual in such cases, but of Sabadini's twelve patients treated internally ten died, while of the eight treated surgically, four survived.

International Congress of Military Medicine

The ninth International Congress of Military Medicine and Pharmacy will be held in Bucharest June 2-10, under the patronage of King Carol. The aims of the congress are (1) to study methods and more practical therapeutic and prophylactic measures in the handling and treatment of the wounded and sick, (2) to maintain and foster good professional relations between the sanitary officers of different nations and (3) to advance suitable methods for the humanization of warfare, by international cooperation. Such congresses have been held at Brussels, Rome, Warsaw, Paris, London, The Hague and Madrid. The committee entrusted with the organization of the congress consists of civil and military medical members, headed by Dr. Iliescu, the surgeon general. The scientific program comprises five problems: 1. The organization and establishment of the activity of the sanitary service in operation in the field and on the sea: England and the United States. 2. The transport, hospitalization and treatment of those wounded by gas: Germany and Yugoslavia. 3. The organization and the function of the surgical service with the motorized troops. 4. The use of the different colorimetric analyses in the laboratory: Switzerland and Japan. 5. Comparative study of the feeding of sick and wounded soldiers in war and peace: France and Turkey. The papers will be published in one of the official languages of the congress: English, French, German, Italian or Spanish. All papers intended to be read at the congress must be addressed to the general secretariat. Membership in the congress, besides the delegates of the respective governments, may include any physician, pharmacist, dentist, veterinary surgeon or administrative officer attached to the territorial, naval or aviation military services. The registration fee to be paid by all who attend is 1,000 lei (\$7.50) for men and 600 lei for women and children. This fee entitles all members to receive the official publications and to partake of all festivities in connection with the congress. Information may be obtained from the Secretariat General, Bucharest II, Institutul Sanitar Militar, Rumania.

Experience with Suboccipital Puncture.

More than 400 suboccipital punctures have been performed by Dr. Maior. This experience has led him to state that the puncture of the cerebellomedullary cistern is without danger when done with adequate precaution and with dexterous hands. From the point of view of outpatient clinics, this method has the advantage of allowing patients to pursue their daily work immediately after the puncture. The timely neurolocalization of syphilis thus effected permits early adequate treatment and a considerable reduction in the number of paralytic and tabetic patients.

Marriages

EVERETT TWEED ALEXANDER, Barnsdall, Okla., to Miss R. Catharine Stephens of Independence, Mo., January 10.

JAMES MARTIN HADEL JR., Richmond, Va., to Miss Allie Bryant Blue of Southern Pines, N. C., March 27.

EDWIN DARRACOTT VAUGHAN, Ashland, Va., to Miss Blanche Van Doran Bashaw of Richmond, April 3.

JOHN HAMILTON SCHERER to Miss Jessie Lee Swisher, both of Richmond, Va., March 29.

SAMUEL HOWARD GARST to Miss Julia Virginia Barber, both of Staunton, Va., April 14.

HERMAN H. HINES, Clinchco, Va., to Miss Dorothy May London in March.

Deaths

George Henry Fox * an Affiliate Fellow of the American Medical Association, father of Dr. Howard Fox, New York, died, May 3, at his home in New York, aged 90, of heart disease. Dr. Fox was born in Ballston Spa, N. Y., Oct. 8, 1846. He was educated at the University of Rochester and received a medical degree from the University of Pennsylvania Department of Medicine in Philadelphia in 1869. After three years of study in Leipzig, Berlin, Vienna, London and Paris, he began practice in New York in 1873. From 1875 to 1879 he was clinical professor of diseases of the skin at the Woman's Medical College of the New York Infirmary and in the latter year went to Starling Medical College, Columbus, Ohio, as clinical professor of diseases of the skin. Two years later he became clinical professor of diseases of the skin and later professor of dermatology at Columbia University College of Physicians and Surgeons, remaining there until 1907. In addition he served as professor of diseases of the skin at the New York Post-Graduate Medical School and Hospital from 1890 to 1895. Dr. Fox was one of six founders of the American Dermatological Association in 1876 and in 1925 was made honorary president. In 1891 he was president of the Medical Society of the County of New York and in 1894 of the Medical Society of the State of New York. He was a member of the American Academy of Medicine and the Royal Society of Medicine of Great Britain. At one time he was consulting dermatologist to the board of health of New York and attending physician to the New York Skin and Cancer Hospital. Dr. Fox and three brothers served in the Civil War. He was the author of photographic atlases on diseases of the skin, a book entitled "Skin Diseases in Children," and "The Lineage of One Hundred American Physicians Named Fox."

Elias Potter Lyon, Minneapolis, for twenty-three years professor of physiology and dean of the University of Minnesota Medical School, Minneapolis, died suddenly, May 4, aged 69, at Trafford, Pa., while returning from a vacation in Florida. Dr. Lyon was born in Cambria, Mich., Oct. 20, 1867. He graduated from Hillsdale College in Michigan and received the doctor of philosophy degree from the University of Chicago in 1897. St. Louis University conferred on him the degrees of doctor of medicine in 1910 and doctor of laws in 1920. He taught at Hillsdale College, Harvard School, Chicago, and Bradley Polytechnic Institute, Peoria, Ill. He was assistant professor of physiology at Rush Medical College from 1900 to 1904 and was assistant professor of physiology and assistant dean at the University of Chicago from 1901 to 1904. He was professor of physiology at St. Louis University School of Medicine from 1904 to 1913 and dean from 1907 to 1913, when he went to the University of Minnesota Medical School as professor of physiology and dean. In 1894 he served as biologist of the Cook Greenland expedition, from 1908 to 1911 investigator for the United States Bureau of Fisheries and investigator during various summers for the Marine Biological Laboratory, Woods Hole, Mass. In 1925 Dr. Lyon was a trustee of the Hillsdale College. He was an associate member of the Minnesota State Medical Association, a fellow of the American Association for the Advancement of Science, and a member of the American Physiological Society and the Society of Experimental Biology and Medicine. He was chairman of the Section on Pathology and Physiology of the American Medical Association in 1934 and 1935 and president of the Association of American Medical Colleges in 1913 and 1914. In 1936 the Elias Potter Lyon Lectureship was established in his honor at the University of Minnesota.

Daniel Paul O'Brien, New Bedford, Mass.; Harvard University Medical School, Boston, 1904; member of the Massachusetts Medical Society and the New England Surgical Society; fellow of the American College of Surgeons; served during the World War; at one time medical inspector in the public schools; visiting surgeon to St. Luke's Hospital and St. Mary's Orphans' Home; for many years medical examiner for the Fourth Bristol District; aged 59; died, February 27, in the Lawrence and Memorial Associated Hospitals, New London, Conn., of cerebral hemorrhage.

Clarence Henry Westgate, Morenci, Mich.; Detroit College of Medicine, 1902; member of the Michigan State Medical Society; past president and secretary of the Lenawee County Medical Society; was secretary of the board of education of Morenci; medical director of the Lenawee County Tuberculosis Sanatorium, Adrian; on the visiting staff of the Detwiler Memorial Hospital, Wauseon, Ohio; on the staff of the Emma L. Bixby Hospital, Adrian; aged 56; died, February 27, of heart disease.

Henry Stevens Tucker * Chicago; Bennett Medical College, Chicago, 1879; demonstrator of anatomy at his alma mater, 1879-1883; professor of surgery, attending and consulting physician to the Bennett College Hospital, 1889-1900; dean and professor of surgical gynecology at the Chicago College of Medicine and Surgery, 1902-1914; for six years attending surgeon to the Cook County Hospital; aged 83; died, April 21, of edema of the lungs, chronic myocarditis and essential hypertension.

James Edmond Coleman * Canton, Ill.; Rush Medical College, Chicago, 1884; past president of the Fulton County Medical Society; fellow of the American College of Surgeons; member, and at one time president, of the board of education; served as volunteer in the American Medical Service Corps during the World War; aged 74; for many years chief surgeon to the Graham Hospital, where he died, March 30, following an appendectomy.

Franklin Uriah Painter, Corpus Christi, Texas; Memphis (Tenn.) Hospital Medical College, 1892; member and vice president, 1917-1918, of the State Medical Association of Texas and counselor of the Sixth District, 1919-1925; fellow of the American College of Surgeons; past president of the Nueces County Medical Society; chief of the surgical staff of the Fred Roberts Memorial Hospital; aged 74; died, suddenly February 4, of heart disease.

Orval James Cunningham, East Cleveland, Ohio; Rush Medical College, Chicago, 1904; member of the Associated Anesthetists of the United States and Canada; formerly associate professor of surgery (anesthesia), University of Kansas School of Medicine, Kansas City; for many years on the staff of the Bell Memorial Hospital, Kansas City, Kan.; aged 57; died, February 23, in the Lakeside Hospital, Cleveland, of cerebral thrombosis.

Harold Bunce Myers * Portland, Ore.; Western Reserve University Medical Department, Cleveland, 1911; associate dean and professor of pharmacology, University of Oregon Medical School; member of the Associated Anesthetists of the United States and Canada; fellow of the American College of Physicians; on the staff of the Multnomah Hospital; aged 50; died, March 16, in St. Vincent's Hospital, of coronary thrombosis.

William Charles Schroeder, Baltimore; University of Virginia Department of Medicine, Charlottesville, 1899; formerly connected with the U. S. Public Health Service; at one time superintendent of the Municipal Sanatorium, Otisville, N. Y., and the Delaware County Tuberculosis Sanatorium, Delhi, N. Y.; aged 61; died, February 18, of coronary occlusion and chronic nephritis.

Arthur Romanzo Weed, New Haven, Conn.; University of Vermont College of Medicine, Burlington, 1912; member of the Connecticut State Medical Society; served during the World War; on the staffs of the New Haven Hospital and the Grace Hospital; aged 54; died, February 7, in Phoenix, Ariz., of arteriosclerosis and nephritis.

Orr L. Perry, Elkins, W. Va.; College of Physicians and Surgeons, Baltimore, 1891; member of the West Virginia State Medical Association; past president of the Barbour-Randolph-Tucker County Medical Society; county public school physician; formerly city health officer; aged 75; died, February 21, in a local hospital, of influenza.

Louis Henry Fales, Livermore, Calif.; Rush Medical College, Chicago, 1897; fellow of the American College of Physicians; formerly surgeon in the U. S. Public Health Service Reserve; on the staff of the Veterans Administration Facility; aged 67; died, February 13, in a hospital at San Francisco, of aplastic anemia.

John Harvey Foster, Michigan City, Ind.; Rush Medical College, Chicago, 1900; member of the Indiana State Medical Association; formerly county coroner; at one time physician in charge of the Indiana Hospital for Insane Criminals and Indiana State Prison; aged 64; died, March 8, of arteriosclerotic heart disease.

Arthur Rudolph Mandel * New York; University and Bellevue Hospital Medical College, New York, 1902; professor of clinical pathology at his alma mater; attending physician and consulting pathologist to St. Vincent's Hospital; aged 60; died suddenly, March 7, at Lake Mahopac, of coronary thrombosis.

John Walter Donaldson * Marietta, Ohio; Cleveland Homeopathic Medical College, 1901; past president and secretary of the Washington County Medical Society; served as a member of the city council and formerly president; formerly health officer; aged 63; died, February 20, of angina pectoris.

Jacob Willis Hill * South Bend, Ind.; Jefferson Medical College of Philadelphia, 1881; past president of St. Joseph County Medical Society; for many years a member of the county board of health; on the staffs of the Epworth Hospital and St. Joseph's Hospital; aged 78; died, February 23.

Eugene Leo Maguire * Somerville, Mass.; Harvard University Medical School, Boston, 1905; member of the New England Obstetrical and Gynecological Society; on the staff of the Somerville Hospital and secretary of its medical board; aged 58; died, February 26, of carcinoma of the lung.

Albert Lawrence Anderson, Brownwood, Texas; University of Texas School of Medicine, Galveston, 1896; member of the State Medical Association of Texas; on the staff of the Stump General Hospital and formerly on the staff of the Medical Arts Hospital; aged 70; died in February.

Ernest Charles Riebel * Chicago; Northwestern University Medical School, Chicago, 1900; formerly instructor in surgery at his alma mater; on the senior surgical staff of the Englewood Hospital; aged 71; died, March 28, in the Albert Merritt Billings Hospital, of morphine poisoning.

Gregorio Singian, Manila, P. I.; University of Santo Tomas College of Medicine and Surgery, Manila, 1896; formerly professor of surgery at his alma mater; medical director of the Hospital de San Juan de Dios; president of the Philippine College of Surgeons; aged 64; died, January 29.

Richard George Wiener, New York; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1878; member of the Medical Society of the State of New York; for many years on the staff of the Harlem Hospital; aged 82; died, February 8.

William F. Hays, Claremore, Okla.; University of Louisville (Ky.) Medical Department, 1890; member of the Oklahoma State Medical Association; past president of the Rogers County Medical Society; aged 70; died, February 26, as the result of a hip injury received in a fall.

John Marshall French * Milford, Mass.; University of Vermont College of Medicine, Burlington, 1877; for twenty-five years on the medical staff of the school board; for many years on the staff of the Milford Hospital; aged 87; died, February 27, of bronchopneumonia.

William Wallace Allen * Mill City, Ore.; Willamette University Medical Department, Salem, 1905; past president of the Polk-Marion Counties Medical Society; bank president; for many years member of the school board; aged 60; died, February 20.

Ezekiel Ezra Smith, Newport News, Va.; Howard University College of Medicine, Washington, D. C., 1903; formerly on the staff of the Whittaker Memorial Hospital; aged 60; died, February 26, of hypertension, myocarditis and chronic nephritis.

Charles Frederick Deacon * Providence, R. I.; Harvard University Medical School, Boston, 1900; for many years surgeon for the city fire department; aged 62; died, February 24, in the Jane Brown Memorial Hospital, of streptococcal septicemia.

Warren Worth Koiner * Beckley, W. Va.; College of Physicians and Surgeons, Baltimore, 1906; served during the World War; on the staff of the Beckley Hospital and the Oak Hill (W. Va.) Hospital; aged 57; died, February 22, of pneumonia.

Joseph H. Hand, Blakely, Ga.; Tallahassee College of Medicine and Surgery, Medical Department of the University of Florida, Jacksonville, 1884; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1887; aged 80; died, February 4.

William Henry White * Goffstown, N. H.; Detroit College of Medicine, 1901; University of Bishop College Faculty of Medicine, Montreal, Que., Canada, 1903; aged 62; died, February 17, of arteriosclerosis and cerebral hemorrhage.

Carl William Forsberg, Minneapolis; University of Minnesota Medical School, Minneapolis, 1923; member of the South Dakota State Medical Association; aged 39; died, February 21, of sarcoma of the hand with metastases to the lungs.

William George Kelly * Bay City, Mich.; Queen's University Faculty of Medicine, Kingston, Ont., Canada, 1897; past president of the Bay County Medical Society; formerly county coroner; aged 63; died, February 17.

Wilbur Mead Holtz * Pittsburgh; Western Pennsylvania Medical College, Pittsburgh, 1903; veteran of the Spanish-American and World wars; aged 61; died, February 27, of streptococcal bacteremia and pharyngitis.

John Jefferson Davis, Madison, Wis.; Hahnemann Medical College and Hospital, Chicago, 1875; since 1911 curator herbarium, University of Wisconsin; aged 84; died, February 26, of coronary thrombosis.

Henry Ermentraut, Watertown, N. Y.; New York Homeopathic Medical College, 1882; United States Medical College, New York, 1882; aged 77; died, February 27, of chronic myocarditis and arteriosclerosis.

John Joseph Cullinan, Hampton, Va.; Lincoln Memorial University Medical Department, Knoxville, Tenn., 1910; served during the World War; aged 48; died, February 26, of pneumonia and heart disease.

John Stone Carlton, Columbus, Ohio; Starling Medical College, Columbus, 1893; member of the Ohio State Medical Association; aged 68; died suddenly, February 28, in Miami, Fla., of heart disease.

William W. Leech, Apollo, Pa.; Jefferson Medical College of Philadelphia, 1880; member of the Medical Society of the State of Pennsylvania; aged 87; died, February 26, of chronic myocarditis.

Chandler Spinx Lynch, Lumpkin, Ga.; Atlanta Medical College, 1914; member of the Medical Association of Georgia; served during the World War; aged 47; died, February 20, of coronary occlusion.

Charles Thomas Harris * Kiowa, Okla.; Chattanooga (Tenn.) Medical College, 1901; aged 66; died, February 7, in a hospital at McAlester, of arteriosclerosis, acute nephritis and hemiplegia.

Guy Franklin Duncan, Sparta, N. C.; Baltimore University School of Medicine, 1902; aged 61; died, February 27, in a hospital at Elkin, of injuries received in an automobile accident.

Christopher Howson, Weaverville, Calif.; University of Toronto Faculty of Medicine, Toronto, Ont., Canada, 1905; aged 63; died, February 7, of bronchopneumonia and influenza.

Robert L. Z. Bridges, Brinson, Ga.; Louisville (Ky.) Medical College, 1894; member of the Medical Association of Georgia; aged 66; died, February 14, of mitral regurgitation.

Jacob Rettich, Cincinnati; Cincinnati College of Medicine and Surgery, 1901; physical director for ten high schools; aged 69; died, February 16, of arteriosclerotic heart disease.

Philip Robert Vivirito * Brooklyn; New York Homeopathic Medical College and Flower Hospital, New York, 1929; aged 34; died, February 2, of carcinoma of the colon.

Hugh Seymour Townsend * Buffalo; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1889; aged 75; died, February 1, of carcinoma of the colon.

Henry Orlando Lacey, Somerville, Mass.; Tufts College Medical School, Boston, 1908; also a pharmacist; aged 56; died, February 9, in Belmont, of cirrhosis of the liver.

John Carlton Riggins * Tucson, Ariz.; Jefferson Medical College of Philadelphia, 1929; on the staff of the Thomas-Davis Clinic; aged 33; died, February 4, of pneumonia.

William Henry Whittle, New Orleans; College of Physicians and Surgeons, Baltimore, 1882; aged 78; died, February 15, of fracture of the femur due to a fall.

Frank Joseph Sedlak, Scranton, Pa.; American College of Medicine and Surgery, Chicago, 1906; aged 63; died, February 14, in the Hahnemann Hospital, of pneumonia.

Edward R. Owings * Baltimore; University of Maryland School of Medicine, Baltimore, 1889; aged 68; died suddenly, February 15, of coronary thrombosis.

John Henry Taylor, Cleveland; Meharry Medical College, Nashville, Tenn., 1919; aged 43; died, February 3, in the Mount Sinai Hospital, of pneumonia.

Eli Shriver Jr., Buffalo; University of Buffalo School of Medicine, 1900; aged 62; died, February 12, in the Sisters' Hospital, of mitral stenosis.

Thomas Alfred Dugdale, South Bend, Ind.; Indiana University School of Medicine, Indianapolis, 1908; aged 53; died, February 11, of pneumonia.

Milton Jay Marsh, Hannibal, N. Y.; University of Georgia Medical Department, Augusta, 1899; aged 60; died, February 21, of heart disease.

William C. Webb * Higginsville, Mo.; Medical College of Ohio, Cincinnati, 1886; aged 73; died, February 1, of coronary occlusion.

Richard James Shute, Windsor, Ont., Canada; Western University Faculty of Medicine, London, 1912; aged 63; died, February 23.

Correspondence

TRICHLORETHYLENE IN MIGRAINE

To the Editor:—A publication by H. S. Rubinstein in the *Archives of Neurology and Psychiatry* for March on the use of trichlorethylene in the treatment of migraine prompts us to communicate briefly our experience with this drug as a therapeutic agent in headache. Attracted by the idea that a volatile medicament might offer a simple means for the prompt relief of headache, we tried trichlorethylene on a small group of patients in February 1936. We selected this drug because of the reports of occasional success with it in the relief of trigeminal neuralgia and angina pectoris.

Trichlorethylene was supplied by the Calco Chemical Company in glass pearls containing 1 cc. of the substance. In the treatment a pearl would be crushed in gauze, placed in the bottom of a drinking glass, and the vapor inhaled by the patient. If relief was not obtained from the first ampule within fifteen minutes, a second was administered; but not more than 2 cc. was given for any one attack. Complete history and physical examination were recorded, and objective and subjective changes were noted in each experiment.

Eighteen severe headaches occurring in fourteen patients were treated with trichlorethylene. The disappointing results obtained in this small group discouraged further investigation of this treatment. The accompanying table summarizes our experience:

Results of Treatment

Migraine attacks (9 attacks in 6 patients)	
Complete relief	2
Uncertain relief	3
Complete failure	4
Nonmigraine headaches (9 attacks in 8 patients)	
Complete relief	2
Uncertain relief	1
Complete failure	6

The six migraine patients were classic cases, and all nine attacks were severe. Only two attacks yielded satisfactorily; i. e., practically complete subsidence of discomfort within thirty minutes. In one patient, three successive attacks were entirely uninfluenced by trichlorethylene. In another subject one attack terminated dramatically, but a subsequent seizure failed to yield to the inhalation.

The nonmigrainous cephalalgias included such cases as menstrual, posttraumatic, fatigue, and sinus or "cold" headaches. Of nine attacks in eight patients, relief was obtained again in only two. Therefore, among the eighteen headaches treated, only four were satisfactorily relieved, and complete failure resulted in more than half of the instances. It is of passing interest to note that the proportion of favorable results is similar to that reported by Glaser (*West. J. Surg.* 39:901 [Dec.] 1931) for tic douloureux. We observed no harmful effects from the inhalations, but symptoms and signs of first degree inhalation anesthesia were usually evident.

Apparently our experience differs considerably from that of Rubinstein, who reported consistently beneficial results in all of his six migraine patients. Further experience will probably allow a better judgment of the value of trichlorethylene in migraine. It is certainly not a specific remedy for migraine, and it is far from being a headache panacea.

Two recent reports adequately review the pharmacology and toxicology of trichlorethylene (Eichert, Herbert: *Trichlorethylene Intoxication*, *THE JOURNAL*, March 9, 1936, p. 1652. Love, W. S.: *Ann. Int. Med.* 10:1186 [Feb.] 1937). The present evidence appears to indicate that relief of pain in angina pectoris, tic douloureux and migraine is probably dependent

on the central sedative and anesthetic properties of this compound. It is true that clinical and experimental poisoning by this agent is less severe than, and differs greatly from, industrial poisoning, and trichlorethylene is apparently less toxic than chloroform. However, it must be remembered that this chemical belongs to, and shares the pharmacologic properties of, the halogenated aliphatic anesthetics. Indeed, it has even been used clinically for complete surgical anesthesia. Despite the fact that no serious untoward effects have been reported from the cautious and proper use of trichlorethylene in the relief of pain, nevertheless in our opinion this drug is not one to be employed indiscriminately or without the knowledge and supervision of the patient's physician.

THE MECHANISM OF EXOPHTHALMOS IN EARLY ACTIVE EXOPHTHALMIC GOITER

To the Editor:—In order to advance my theory of exophthalmos in exophthalmic goiter, based on 300 operative cases from September 1924 to March 1937 (a twelve and one-half years period) it is necessary to agree on certain fundamentals:

1. That the exophthalmos is due to exophthalmic goiter.
2. That exophthalmos is usually bilateral and in some relation to the severity of toxicity.
3. That exophthalmos usually subsides when toxicity is removed.
4. That exophthalmos is less frequent (60 per cent in my cases) since the advent of compound solution of iodine and since patients come early for surgery.

As the condition has not been understood, and as the literature is flooded with varied theories, my explanation to be tenable should have the following requisites:

1. It must explain the varied anatomic physiologic and pathologic changes, beginning with the first eye sign, the stare, and covering the varied degrees of exophthalmos. (The malignant type with the changes of toxicity preoperatively and postoperatively will be taken up in my complete report.)
2. It cannot contradict any of our proved facts.
3. It must not violate Pascal's law.

With the increased activity of the thyroid in the early phase of exophthalmic goiter there is a stimulation of the nervous system, particularly the sympathetic (tremor, sweating, redness of skin). The first manifestation of sympathetic stimulation in the eye is the stare due to retraction of the upper lid (Stelwag's sign) from an involuntary continued contracture of the levator palpebrae superioris. This muscle, arising above and in front of the optic foramen, runs forward and ends anteriorly in a wide aponeurosis, which splits in three lamellae. The superficial lamella blends with the palpebral fascia (orbital septum; torso-orbital fascia); the middle lamella (largely non-striped muscle) is inserted into the upper margin of the tarsus; the deepest lamella is attached to the superior fornix of the conjunctiva.

Moderate continued contracture of this muscle at first just takes up the slack in the orbital septum and exaggerates the elevation of the upper lid, producing the characteristic stare. Soon it retracts the palpebral fascia (orbital septum), stretching it backward (intra-orbitally), thereby slightly raising the intra-orbital pressure. This gradually adjusts itself by a slight forward movement of the eye, and, as the muscle spasm continues, the fascia retracts further, the pressure adapting itself by more

protrusion of the eye, finally resulting in a noticeable exophthalmos. While this phenomenon is going on, the crowding of the lid against the stretched orbital septum somewhat impedes drainage of the orbital tissue spaces, and a mild edema begins, which further accentuates the protrusion.

ROBERT E. MORAN, M.D., Washington, D. C.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

URTICARIA WITH ANGIONEUROTIC EDEMA

To the Editor:—The following is the history of a patient whose condition has me "stumped." I would appreciate any suggestions you might make as to diagnosis and treatment: A white man, aged 34, weighing 143 pounds (65 Kg.), has repeated attacks of localized swelling of the skin. The swollen areas vary from the size of a pea to irregular areas the size of the palm. Most of the swollen areas, however, are about the size of a walnut to the size of an egg. Although these swollen areas may appear on any part of the skin, they are most prevalent on the back and especially along the spine (about 1 or 2 inches from the spinuous processes). The areas are pale red, feel somewhat indurated, do not itch (occasionally a very slight itching may be present), and are not tender or painful except when they involve a joint. The joints most likely to be affected are the knees, ankles and joints of the feet. During the attacks, when these wheals appear, any slight scratch, pressure or trauma to the skin will produce a welt. The shoulder strap of a fishing tackle box or an ordinary belt about the hips will produce a welt on the skin for the full extent of the strap. Welts appear on the forearm when pressure is made by boxes or furniture that he may be carrying. The individual welts last one or two days and then disappear, although the period during which they may arise may be of two or three weeks' duration. He is now in the fifth attack of this condition; the first was in the spring of 1935, when it seemed that only joints were involved (feet, ankles and knees), the second in the spring of 1936, the third in November 1936, the fourth in January 1937, and the fifth in February 1937. The fourth attack followed his investigation of a leaking roof in the attic. He pulled himself up through a small trap door entrance to his attic and walked about on the cross beams in his thin-soled house slippers. The following day he noticed large areas of swelling of the posteromedial aspects of both arms where they had borne his weight in pulling himself up through the trap door, and he noticed that there was increasing pain and swelling in the region of the inner arches of the feet. Numerous other areas of localized swelling were present on the extremities and trunk. He was given 0.7 cc. of epinephrine solution (1:1,000) with no effect after a period of four hours. All symptoms disappeared in three days.

The patient came to my office two days after the onset of the fifth attack (about one month after the fourth attack). The lesions in this attack differed from those of former attacks. They were predominantly on the back but were more scattered over the region of the scapulae and small of the back rather than along the spine, where they had formerly predominated. There were a few scattered over the legs, arms and wrists. The lesions themselves differed from the former ones in that they were smaller, varying from a pinhead to a 50 cent piece (30 mm.). Instead of being rounded they were flat on top (the edges as high as the center); the peripheral boundaries were more irregular or serrated; the lesions were bright red, whereas former lesions were slightly pinker than the surrounding skin; the centers of the larger lesions were clear or pale, giving a ring or horseshoe appearance; the larger lesions were elevated about 3 or 4 mm. above the surrounding skin; there was more itching, not intense but slightly annoying. By the end of the third day the lesions had practically disappeared, but the right foot began to swell and in an hour's time was so swollen that he could not put on his shoe. This swelling lasted for two days. The swelling involved only the foot, there being no involvement of the ankle. There was no swelling in the left foot. At the same time there was slight swelling in the right knee, and pain appeared in the knee as the swelling subsided. No heat or redness in the swollen areas occurred.

The patient gives no history of allergy to any food except strawberries. He was not sensitive to strawberries before 1935 and since that time has eaten them only twice with an urticarial reaction each time. He has taken calcium gluconate and cod liver oil concentrate daily since the attack in November 1936. He had previously been on alkalis and a diet of fruits and vegetables (no meat or acid-producing foods) for a period of three months with no effect on the condition. He seems perfectly well during these attacks except possibly for a little loss of "pep." His wife believes that she can predict the approach of an attack because "he looks a little pale." He is of the slender, energetic type. Until the past year or so he was quite active in athletics, such as basket ball, baseball and volley ball. The physical examination is entirely negative except for a slight dermographic reaction. The temperature and pulse are normal throughout the attacks. Urinalysis is negative. He is the manager of a furniture store. He has always been in good health. He

had measles, pertussis and chickenpox during childhood. He had inflammatory rheumatism and typhoid at 7 years of age. He had an attack of rheumatism in the knees lasting but a few days in the fall when 8 and again at 9 years of age. He did not have chorea or tonsillitis. There have been no operations, symptoms referable to gastro-intestinal, genito-urinary or cardiovascular disease or to disturbances of the respiratory system. No weight loss has occurred but he cannot gain weight. The bowels move regularly without laxatives. There is no history of hay fever or asthma. He does not use alcohol. He smokes one package of cigars a day. He sleeps well. His father, one brother and one sister died of tuberculosis. One sister was in a sanatorium eight years with tuberculosis and was dismissed two years ago as cured. The mother died of carcinoma. There is no history of any allergic condition in the family. I was of the opinion that the condition was a type of angioneurotic edema until I found that there was no change in the lesions after injection of epinephrine solution. The patient is an intelligent, well educated man, constantly watching his diet and environment for something that may be producing the condition. He is distinctly not of the neurotic type unless I am badly fooled.

M.D., Indiana.

ANSWER.—The description of this condition speaks strongly for urticaria combined with angioneurotic edema. The fact that the patient may not obtain relief from injections of adequate amounts of epinephrine solution is not a valid enough objection to this diagnosis. Epinephrine is frequently without effect in urticaria. Even in asthma it may fail to produce relief. The fact that the patient is definitely sensitive to one known food, even though it is such a commonly accused food as strawberries, suggests that the source of these attacks may also be due to definite protein sensitivity.

The determination of the cause of urticaria is at times one of the most difficult problems for even a seasoned allergist. The following outline of causes is therefore offered as a guide for further work:

1. Ingestant factors: (a) Any food may be a cause. Often a patient blames meat when the onions or pepper used for flavoring is the cause. (b) Drugs are often overlooked. The commonest are acetylsalicylic acid and its derivatives, phenolphthalein, quinine and the iodides (iodized salt).
2. Contact substances: These are too numerous to mention. An intelligent study of the occupation and hobbies of the patient is necessary in each case suspected of belonging in this group.
3. Infections: (a) Focal infections in the sinuses, gallbladder or appendix, not frequent causes. (b) Infections caused by epidermophytosis, one of the commonly undiagnosed causes. A close inspection of the toes with the finding of definitely active lesions of a ringworm infection may lead to the presumptive cause. The added proof required is for the urticaria to disappear with the successful clearing of the ringworm infection.
4. Parasites: (a) Scabies may occasionally cause urticaria. (b) The stools should be examined, especially in the presence of diarrhea or other gastro-intestinal complaints. Freshly passed stools or mucus from the intestine may be necessary in some of the suspected but rare causes of urticaria (amebiasis). An unusually high blood eosinophilia may suggest stool examinations.
5. Endocrine dysfunction: This may be a cause of urticaria. It is not as common a cause in males as in females. Thyroid dysfunction, usually hypothyroidism, but possibly also hyperthyroidism, may be a cause of the condition.
6. Physical causes: Light (urticaria solare). Heat. Cold. Trauma: This (urticaria factitia) was probably an aggravating factor during the fourth attack. The physical causes are considered by some authorities as frequent primary causes of urticaria. Others consider them usually as secondary, or factors that aggravate an attack in the presence of other primary causes.

7. Psychogenic causes: Possibly the most likely group into which such a patient falls is the "ingestant" group. Drugs should be carefully ruled out as a cause. Foods may then be studied by intradermal tests. (Scratch tests rarely work. Intradermal tests react in from 25 to 50 per cent of the cases.) Positively reacting foods should be completely eliminated from the diet. It may be necessary to go further into the allergic study by using the method of diet diaries. (Study by the elimination diet does not fit this case because of the infrequency of the attacks.) A study should be made of foods eaten for twenty-four hours before the onset of an attack and especially during the meal preceding the attack to see whether any food is sufficiently unusual to be suspected. Should these measures fail, the worker may resort to leukopenic index studies of suspected foods when skin tests are of no aid. The technic has been described in several recent articles by Warren T. Vaughan on this subject (*J. Allergy* 5:601 [Sept.], 6:78 [Nov.] 1934, 421 [July] 1935; *J. Lab. & Clin. Med.* 21:1278 [Sept.] 1936).

TREATMENT OF SYPHILIS

To the Editor:—A white woman, aged 25, consulted another physician in April 1931 for a blood Wassermann test following a suspicious contact and before any symptoms had appeared. The reaction was positive and nearsphenamine therapy was instituted. One year later, after thirteen intravenous injections, with appropriate rest periods, the blood Wassermann reaction was negative. Because of some sort of idiosyncrasy to nearsphenamine, that drug was discontinued, and a bismuth compound was started. Between 1932 and the present time the patient has received 130 bismuth injections (deep, intragluteal) and seven of colloidal mercury sulfide by the same route. The patient has had no complaints at any time, and the blood Wassermann reaction has been persistently negative. It is felt that the initial test on the blood was correct because it was repeated twice thereafter before treatment was begun. Will you please comment on (1) whether this patient has received enough antisyphilitic treatment to be considered cured, (2) whether the disease process may be considered permanently arrested, and (3) whether mercuric therapy should be continued and a lumbar puncture for examination of the cerebrospinal fluid done in spite of the absence of symptoms. Please omit name.

M.D., Florida.

ANSWER.—1. The patient has not received what is now considered the minimum amount of treatment necessary to cure a patient with early syphilis. However, patients do not all respond alike to the prescribed number of injections, because in a few cases cure is obtained with less than the recommended amount, while in others two or three times this amount of treatment fails to produce cure. From the information given in the inquiry it appears that the Wassermann reaction has been negative for approximately five years, and if the spinal fluid is also negative the patient may be placed in the "cured" group.

2. Accordingly, the disease process may be considered arrested provided the spinal fluid is negative. Nevertheless, as this young woman is still in the child bearing age, it would be advisable to warn her of the necessity of undergoing further treatment should she become pregnant. The Cooperative Clinic Group studies have shown that in 17 per cent of the women with latent syphilis and negative blood serologic reaction syphilis has interrupted the pregnancy or resulted in the child's having the disease. Hence adequate treatment is indicated throughout the pregnancy even though the patient had sufficient treatment before the conception to render the reaction negative.

3. It is urged that the patient's spinal fluid be examined now although the reaction on the blood is negative and she is asymptomatic. If the spinal fluid test is negative, no further treatment is necessary, whereas if the report is positive, specialized treatment will be warranted.

RENAL GLYCOSURIA

To the Editor:—A man, aged 26, in good health, consulted me because of a positive urinary sugar. This condition was first noticed at least six years ago, at which time he was turned down for insurance. There are no symptoms whatever of diabetes mellitus. The urine shows dextrose in about 50 per cent of the specimens, while the other 50 per cent are negative. The highest recorded amount of dextrose has been 0.4 per cent. In November 1934 the blood sugar, on a fasting stomach, was 86.2 mg. per hundred cubic centimeters of blood. More recently the fasting blood sugar was 100 mg. and the urinary sugar was negative. Two and one-half hours after 100 Gm. of dextrose by mouth, the blood sugar was 64.5 mg. and the urinary sugar 3 plus. I would appreciate your opinion as to the significance of these observations and whether or not this patient should be classed as a true diabetic or one with a renal glycosuria. Please omit name.

M.D., Tennessee.

ANSWER.—The range of the normal fasting blood sugar is from 80 to 120 mg., with an average of 100 mg. per hundred cubic centimeters of blood. More recent modifications by Folin and by Benedict give results from 20 to 30 mg. lower.

Any glycosuria in a patient with a fasting blood sugar below 110 mg. is probably unimportant and not diabetic. Values up to 140 mg. may be obtained in acute infectious diseases, especially pneumonia, focal infections, hypertension and arthritis. Variations with values slightly above normal may occur in disorders of the ductless glands (thyroid, pituitary) other than the islets of the pancreas.

Mild diabetes is usually associated with fasting blood sugar from 150 to 250 mg., while the more severe types show between 250 and 600 mg. or higher. An elevation of long duration is characteristic of diabetes; a quick rise and decline are characteristic of hyperthyroidism, acromegaly and hyperadrenalism.

Sugar is usually eliminated by the kidneys when the blood sugar reaches from 160 to 180 mg., except in some cases of renal disease. In normal persons the blood sugar seldom rises above 140 mg. after an average meal. After excessive sugar intake an alimentary glycosuria may occur in a normal person.

Renal glycosuria is characterized by a normal blood sugar and usually less than 1 per cent of sugar in the urine. The sugar in the urine does not vary much with the amount of

carbohydrate ingested. Most cases of renal glycosuria remain benign; there is often a hereditary tendency. After a number of years, diabetes develops in a few cases.

A fasting blood sugar above 120 mg. per hundred cubic centimeters with glycosuria indicates diabetes. The maximum normal blood sugar in a sugar tolerance test (ingestion by an adult of 100 Gm. of dextrose) should not exceed 180 mg. at one hour and should drop to 140 mg. at two hours. In diabetes mellitus the curve shows over 150 mg. in two or three hours. A fasting blood sugar below 120 mg. with a rise to 200 or over after one hour, and return to 120 or lower in two or three hours, suggests hyperthyroidism or hyperpituitarism.

When a low renal threshold can be demonstrated as in the case cited, with a fasting blood sugar of 86.2 mg. and return to 64.5 mg. in two and one-half hours, the glycosuria must be considered benign. When there is a rise to an abnormal height after the ingestion of 100 Gm. of sugar, one must be more cautious. A diabetic curve is abnormally high throughout. The patient does not have true diabetes; he has a so-called renal glycosuria. A sugar tolerance test with one sample of blood before and other samples one, two and three hours after ingestion of 100 Gm. of dextrose should be done.

USE OF TRUSS IN HERNIA

To the Editor:—There has been some dispute as to the value of a truss in a femoral hernia. Should a man with a femoral hernia be advised at all to wear a truss? If a truss is worn is there any possibility of cure, such as might occur in an indirect inguinal hernia? Please omit name.

M.D., New York.

ANSWER.—One having a femoral hernia should be advised not to wear a truss but to be operated on unless there is some strong contraindication, such as a poor operative risk.

In any irreducible hernia a truss should not be advised. Conditions are somewhat different in a reducible femoral hernia from those in an indirect inguinal hernia, in which a properly fitted truss pad may be placed over the internal ring. Adhesions may form with clinical cure in a child or adolescent, but a certain number may recur at a later period if the truss is taken off.

When the truss pad is placed over the external ring in an inguinal hernia, the viscera may be prevented from coming out but no cure will result. Similarly, the use of a truss in a femoral hernia may prevent the hernia from coming out but owing to the strong Poupart ligament it is impossible to compress the femoral canal and obliterate it. If it should be attempted, the underlying blood vessels might be damaged and a thrombophlebitis or thrombus formed.

It is possible by means of a small downward steel extension to a spring truss frame to hold a pad over the femoral canal and to maintain some pressure. It is difficult to keep a constant pressure unless one is particularly fortunate in the mechanical fitting of the truss, which is difficult. The usual result is that the pad does not keep the hernia from coming out under ordinary exercise or working conditions.

When a hernia is not completely reduced, adhesions of the omentum or bowel are likely to form in the sac with incarceration, which prevents complete reduction.

A femoral hernia is rarely continuously held up with a truss; consequently there is frequent danger of strangulation.

COMBATING SNAKE BITE

To the Editor:—Please inform me of the most practical means for combating snake bite in Central American countries, specifically the republic of Honduras. What commercial kit, for travel, can be recommended and are there any antivenom serums that do not deteriorate if not refrigerated or kept reasonably cold? Please omit name.

M.D., Virginia.

ANSWER.—There is one efficient and now well tested method of treating the bite of our pit vipers—moccasins, copperheads and rattlesnakes—and that is (1) the immediate shutting off of the lymphatic circulation by a ligature, not too tight, around the extremity, leg, finger or arm, immediately above the swelling from the hemolyzed extravasated blood; (2) cruciform incisions through the skin at the fang punctures, with further similar incisions about three-fourths inch apart wherever there is any swelling, and (3) suction applied to such incised areas for about half an hour to extract the laked blood with the venom. If the swelling extends, the ligature should be placed higher up and the incisions and suction continued, the latter for at least twenty minutes out of every hour so long as swelling persists. This vital performance is sometimes facilitated by injecting a mild saline solution into the tissues to promote the outflow. Where much of the poison has been absorbed

and the patient is profoundly affected, antivenin may be useful, but it must be given in far greater doses than heretofore advocated; that is to say, five, ten and fifteen ampules. A single ampule is of no use. Credit for this new and wonderfully efficient method of treatment is due Dr. Dudley Jackson of San Antonio, Texas. The simple extraction outfit can be secured from the Flack Drug Company of San Antonio or from sundry other firms.

If the patient is bitten by a coral snake, such a method would not be effective unless applied at once after shutting off the circulation temporarily; this is conjectural. There is no other remedy.

RECURRENT PYREXIA AFTER LAPAROTOMY

To the Editor:—A woman, aged 36, married, with one child who is 7 years of age, had a left-sided nephrotomy sixteen years ago with no serious illness up to the present time. In the middle of February 1936 she noticed that she had a fever. I saw her in my office March 5, complaining of (1) headache, either two days before or after menses or half-way between, (2) backache, (3) pain in the lower part of the abdomen, (4) pain in the right groin, (5) pain in the chest, usually before the menses, and (6) fever for the past two weeks. Physical examination revealed blood pressure 114 systolic, 70 diastolic; pulse 74; temperature 99.1; heart normal; chest clear; throat normal. There were two decayed teeth (left lower molars). Pelvic examination revealed marked inflammation of both tubes, retroversion of the uterus and tenderness over McBurney's point. A diagnosis of pelvic inflammatory disease and subacute appendicitis was made. March 25 a laparotomy was done, consisting of bilateral salpingectomy, appendectomy and a ventral suspension. Recovery was uneventful, and the patient left the hospital with practically a normal temperature. She still continues at this date to have a fluctuating temperature. Her blood count is normal; repeated urinalyses give normal results; tests for tubercle bacilli in the urine are negative; roentgenograms and physical examinations of the chest are negative for tuberculosis, and roentgenograms of the kidneys are normal. The patient is 5 feet 5 inches (165 cm.) tall and weighs 86 pounds (39 Kg.) with her house clothing on. She feels well in every respect. She is now rid of all her complaints, except for the fever. Kindly omit name.

M.D., Pennsylvania.

ANSWER:—If one assumes that all grossly diseased pelvic organs were removed at the time of the laparotomy and that pelvic examination is negative at present, it seems entirely improbable that pelvic infection is responsible for the present low grade fever. Cervicitis alone almost never produces fever; chronic endometritis and metritis are rarities; oophoritis ordinarily manifests itself by pain, tenderness and menstrual dysfunction, none of which the patient has. Long continued postoperative fever should always bring to mind the possibility of an overlooked sponge. Since the correspondent has investigated the common sources of fever, the problem now resolves itself into a study of obscure chronic pyrexia. This subject has been discussed and references were cited by THE JOURNAL, Sept. 7, 1935, page 803, and Sept. 28, 1935, page 1059. Among the possibilities to be considered further are undulant fever, rheumatic infection, endocarditis, focal infections (nasal sinuses, mastoid, middle ear, teeth, gallbladder), syphilis, Hodgkin's disease, tuberculosis, hyperthyroidism and psychogenic fever. It is essential that a reliable chart be kept showing the temperature three or more times a day over a period of several weeks. If no diagnosis can be reached, a regimen designed to increase the patient's weight will probably benefit her and may incidentally lead to a normal temperature.

"MISTER" OR "DOCTOR" AS ADDRESS FOR BRITISH SURGEONS

To the Editor:—Would you kindly, without publishing my name, publish in Queries and Minor Notes the reasons surgeons are addressed as "Mister" in England and physicians as "Doctor." Possibly the distinction is not as clean cut as I surmise, but I should like to know the origin of the difference.

M.D., Duluth, Minn.

ANSWER:—The terms Doctor and Master were interchangeable and of equal value in the earliest medieval universities. In process of time the faculties gave the degree of Doctor and Bachelor. These continued but the Master in Surgery dropped out, partly because there were no candidates and partly because surgery came to be looked on as an inferior branch divorced from physic. Graduates who practiced as what would now be called surgical consultants were content to use the term magister. Peter Lowe of Glasgow was always known as Maister Peter Lowe at the end of the fifteenth century. John Arderne, the father of English surgery, had gone one better 200 years earlier, for he began as John Arderne, became Maister John Arderne and ended, when he settled in London, as Maister John de Arderne. In the seventeenth century a doctor of medicine was a university graduate like Dr. Radcliffe or Dr. Mead. We

know from the novelists of the eighteenth century that the term was still in restricted use, for when a medical man is called in he is surgeon So and So, Mr. Blank or the Apothecary, and all were treated with scant respect. Territorial restrictions were abolished in the nineteenth century and many Scottish graduates settled in England. They usually held the M.D. degree and after their arrival the use of the word Doctor became generic and appeared to be so desirable that some of the English licensing bodies allowed their members to use it as a courtesy title. The term Master was retained by consulting surgeons as a continuation and contraction of Magister; when it is used by a general practitioner it is a term of respect, a mere variation of the older form of Measter, just as the last generation spoke of Mrs. as Mistress So and So, but except for surgeons, Mr. is rapidly being replaced by Dr.

TREATMENT OF NEUROSYPHILIS

To the Editor:—Paralysis of the oculomotor nerve has occurred, as evidenced by ptosis of the lid (left eye), inability to move the eyelid medially, and dilatation of the pupil. This results in double vision unless one eye is closed. It came on suddenly, Oct. 18, 1936. Syphilitic infection occurred over twenty years ago; the patient is now 60 years of age. Some intravenous treatment was given ten years ago. Vision in both eyes was not good for many years prior to the present condition. There has also been some tremor of the hands but no disturbance of gait or mental condition. To date this patient has been getting ordinary treatment with neosarsphenamine, a bismuth compound and potassium iodide since the onset of the acute eye muscle paralysis. I wish to know whether it is advisable to give tryparsamide. If it is or is not given, what is the outlook for any improvement in the paralysis of the eye muscles?

G. L. RATHBUN, M.D., New Windsor, Ill.

ANSWER:—When an oculomotor palsy does not clear up in from six to eight weeks, it is rather unlikely that it will do so later, irrespective of the type of treatment used. Tryparsamide is unquestionably more efficacious in treating syphilis of the central nervous system than either neosarsphenamine, bismuth compounds or potassium iodide and would be definitely indicated in this case except for the possibility of damage to the optic nerve. There is a difference of opinion as to the advisability of using tryparsamide in optic atrophy. It is wiser, however, in most instances not to attempt to use this drug if atrophy has occurred.

In the case under discussion there is no evidence of optic atrophy, but rather evidence of some disturbance in the media. As arsphenamine is more likely to cause disturbances of the media than does tryparsamide, it would seem reasonable to switch to the latter drug. This should be given, however, in small doses, e. g., 1 Gm., for some time, and during this period the eyes should be watched very carefully from the standpoint both of subjective and of objective changes.

EFFECTS OF CLIMATE, PARTICULARLY SEASHORE; ON HYPERTENSION

To the Editor:—I have noticed that several of my patients who have spent a long time at the seashore returned with a higher blood pressure than when they left the city. Recently a patient of mine, aged 60, suffering from diabetes mellitus, whose blood sugar has been reduced from 450 mg. to 220 mg. and who felt very well under insulin treatment and whose blood pressure was 165/110 for about two years, returned from a three months vacation with a blood pressure of 230/120. The insulin treatment was continued during her vacation. Has it also been your experience to find that the salty air and absolute lack of exercise has the same effect on a patient?

SIMON STEINBACH, M.D., New York.

ANSWER:—So far as is known, the "salty air" of a seashore resort has no appreciable effect on the arterial tension one way or the other. Absolute lack of exercise, on the other hand, may be a significant factor. H. O. Gunewardene (High Blood Pressure and Its Sequelae, Baltimore, William Wood & Co., 1935) has emphasized that physical inactivity plays an important part in hypertensive arterial disease in India. Hypertension rarely occurs among rickshaw runners, who take violent exercise with long and exhausting hours, whereas it is notably common among certain social groups who habitually lead sedentary lives with overeating. It is also conceivable that this and similarly affected patients tend to overeat while residing at the seashore. Anxiety, worry and mental fatigue also may be factors; it is not justifiable to assume that, because the stay is called a vacation, mental relaxation necessarily follows. Careful questioning of these patients as to sources of annoyance, irritation or fear is advisable before one can attribute the change to climatic conditions. For example, it has been observed that the similar episodes finally proved to be due to the fact that the patient had been playing cards for stakes beyond her means.

at a mountain, not seashore, resort. Changes in environmental temperature may be associated with changes in the arterial tension without a doubt; cold causes the pressure to rise and hot weather is associated with a drop. In isolated instances such exacerbations as were noted with the patients returning home from the sea may be due to transient infections while away. The arterial tension, notoriously labile even in normal persons, is always more readily raised than lowered in those with hypertensive arterial disease. In an individual constitutionally vulnerable, any number of factors may precipitate exacerbations or recurrences of the hypertension. It is primarily for this reason that hypertensive arterial disease must be considered as possibly controllable but not curable.

LOW RESIDUE AND HIGH RESIDUE DIETS IN HEMORRHOIDS

To the Editor:—In the past it has been taught that high residue, bulky diets are indicated in the treatment of constipation. However, one of my patients had a hemorrhoidectomy a few months ago and she tells me that she was advised to continue a smooth diet indefinitely. She states also that her physician told her that a low residue, high protein menu will act as a stimulant to peristalsis. Which of these views is the correct one?

J. B. STOKES, M.D., Ottawa, Ill.

ANSWER.—The balanced American diet calls for a proper adjudication of residue and nonresidue foods. It has been amply proved and substantiated that the continued use of a bland diet over a long period commonly results in an intolerance of the intestinal tract for the residue bearing foods later infiltrated into the diet.

The use of high residue, bulky diets for the treatment of constipation is still indicated when a state of atonicity is the etiologic factor. However, in cases of constipation of spastic origin such a diet is not only contraindicated but is capable of increasing the presenting condition.

In the light of present knowledge it is not reasonable to suppose that a low residue, high protein menu will act as a stimulant to peristalsis. It must be borne in mind, however, that a high protein menu would of necessity involve the ingestion of approximately 100 Gm. or more of protein, derivable mainly from meat, fish, cheese and eggs. It is barely possible that the fiber contained in large quantities of meat would provide sufficient residue to act as an intestinal stimulant.

INDIGESTION AND TUBE FEEDING

To the Editor:—In handling psychotic patients who refuse food I am in the habit of giving them a feeding by stomach tube either once or twice daily. I find that often, as a result of this tube feeding, patients develop diarrhea and I am anxious to learn whether there is something wrong with the formula that I use or whether there is any particular ingredient that is not used properly or used to excess. The tube feeding formula consists of four eggs, 4 ounces of butter, 2 ounces of sugar and 20 ounces of milk. In addition to this feeding, which is approximately 1 quart, 1 ounce of cod liver oil and 1 ounce of tomato juice and several grains of concentrated yeast are poured down the tube. I estimate that the total value of such a feeding is about 2,000 calories. In cases in which I feel that 1 quart is too much to give at one feeding I divide the amount into two feedings. I would appreciate an opinion from you as to whether there is something in this formula that causes the diarrhea. Any suggestions along this line will be appreciated. M.D., New York.

ANSWER.—A rough evaluation of the feeding stated reveals the administration of approximately 175 Gm. of fat, yielding about 1,600 calories, to the feeding.

It would appear evident that this amount of fat in a total caloric yield of about 2,300 calories is entirely too high.

It appears most likely that the proportionate mass of fat administered is probably responsible for the intestinal irritative symptoms.

OPACITY OF CORNEA

To the Editor:—I have as a patient an infant, 4 months of age, with a congenital malformation of the left eye which, as far as I can tell, is a complete corneal opacity. The child has been seen by a competent ophthalmologist, who told the mother that there was no hope of vision but that a glass eye could be inserted later because of the disfigurement. If the eye is useless, could not the disfigurement be corrected by other means, as by tattooing a pupil? Has a glass pupil, similar to a contact lens, ever been used? Please give references in answer. M.D., New Jersey.

ANSWER.—Congenital opacity of the cornea may vary from merely a thin leukoma to the complete opacity here described. The condition has been studied extensively by von Hippel, Peters, Clausen, Fuchs, and others (see *Kurzes Handbuch der Ophthalmologie*, vol. 4) and there is no unanimity of opinion as to the cause. In later life, colored tattooing by the Holth

method might be successful, but the suggestion of using a thin artificial glass shell eye over the eyeball is the most practical. A "glass pupil similar to a contact lens" is out of the question.

HEREDITARY KERATOSIS PALMARIS ET PLANTARIS

To the Editor:—What, if anything, can I do for a case of congenital and hereditary keratosis palmaris et plantaris? My patient, a girl aged 6, is of the third generation to suffer from this malady, her father and his mother being likewise troubled. Two other children, a brother and sister, do not have the disease. Salicylic acid ointments and other remedies have helped little, if any. I have not employed constitutional treatment of any kind. Are the x-rays of any benefit? If so, what dosage should be employed? N. H. FARRELL, M.D., American Falls, Idaho.

ANSWER.—Complete relief in congenital and hereditary keratosis palmaris et plantaris is rarely accomplished. The patient can be made comfortable and the skin kept soft by treatment. The use of from 3 to 10 per cent salicylic acid in petrolatum, together with prolonged maceration of the parts in water and rubbing with bland soaps, is of value.

In such cases in adults associated with low basal metabolic rates the use of thyroid by mouth is sometimes of value in addition to other treatment. X-rays have been used with beneficial results in these cases. Response to the latter is variable, however, and in view of the recurrence of the condition they must be used with great caution to prevent the likelihood of a radio dermatitis supervening. Single suberythema doses, cautiously given with a well calibrated machine may be used.

In a child, however, it would probably be wiser to give a fractional x-ray exposure of from 50 to 75 roentgens at five to seven day intervals for four to six exposures. A long rest period should be allowed before repeating the dose.

SAFETY OF THE SHOE-STORE FLUOROSCOPE

To the Editor:—Your answer on "Safety and Utility of Fluoroscopy" (*THE JOURNAL*, March 27, p. 1134) brings forth the question of the safety of the shoe store fluoroscope, such as that used by the local shoe firm to which I send my patients. While the shoe people find these instruments extremely useful in checking fittings, especially for children, I have wondered with regard to the safety with which they may be employed. Is there any way to determine the escape of dangerous irradiation?

M.D., Michigan.

ANSWER.—Shoe store fluoroscopes have less value in connection with the fitting of shoes than may appear on the surface. Their value is chiefly commercial, because they make a considerable impression not only on the customer but also on the dealer. As for their safety, exact data are not available. It is probable that the time required for the average fitting is short enough to make any real danger slight. Nevertheless, the possibility of danger is there. To determine the margin of danger present would require accurate physical measurements which to our knowledge have not been made.

DERMATITIS HERPETIFORMIS

To the Editor:—A man, aged 50, has a chronic dermatitis, which began three years ago. A diagnosis of dermatitis herpetiformis was made by me and confirmed by a well known dermatologist. The patient has no other complaint, there are no obvious foci of infection, and his general physical examination is negative except for the skin lesions. Treatment has consisted of various lotions of the calamine mixtures with solution of coal tar and other local treatment of similar nature, sodium cacodylate both intramuscularly and intravenously, neoarsphenamine intravenously, a series of autogenous colon vaccine, and many lotions and ointments prescribed elsewhere. Realizing how persistent and practically incurable this condition is, I nevertheless would appreciate any further information as to subsequent treatment that might benefit this man. Please omit name.

M.D., Kansas.

ANSWER.—The response to therapy in dermatitis herpetiformis is variable. All foci of infection should be ruled out, including the prostate. The use of dicalcium phosphate by mouth with vitamins A and D is of value. Calcium may also be given by intramuscular injections as calcium gluconate. The intramuscular injections of 10 cc. of the patient's own blood (auto-hemotherapy) at intervals of from three to five days is of value in many of these cases. Arsenic may be employed again in the form of solution of potassium arsenite, beginning with small doses and gradually increasing to the physiologic limit. The urine should be carefully watched during the arsenic administration. Salicin in 1 Gm. dose, thyroid and antipyrine have been employed. X-ray exposure of the spinal region was used with success by H. R. Foerster (*Arch. Dermat. & Syph.* 25:256 [Feb.] 1932).

Locally, the use of lotions containing phenol or menthol, or ointments containing sulfur is recommended. Soothing effects

are further obtained by alkaline, bran or oatmeal baths, or the use of a bath to which from 4 to 6 ounces of solution of sulfated lime (Vleminkx's solution) has been added.

A simple diet with moderate exercise and regular habits of living, together with nervous and emotional calm, is essential to successful therapy.

SENSITIVITY TO ARSPHENAMINE

To the Editor:—I have a patient with syphilis who is sensitive to arsenic. I have tried nearsphenamine, mapharsen and bismarsen and all produce a severe dermatitis. Sixteen bismuth intramuscular treatments have not changed the 4 plus Kahn reaction. Can you suggest any other arsenical that will not produce a dermatitis? If not, what would you advise as to treatment? Please omit name. M.D., Illinois.

ANSWER.—This patient is apparently intolerant of arsenic and further effort should not be made to give arsphenamine or any of its various modifications for some time to come. It would be advisable to examine the spinal fluid, to check the cardiovascular system for evidence of syphilitic aortitis, and to seek other manifestations of syphilis in the viscera or mucous membranes as the cause of the persistently positive Wassermann reaction before pushing ahead with treatment. If these examinations are negative, injections of a bismuth compound, at least two courses annually of twenty injections each, should be given for a period of four or five years.

As data with regard to the sex and age of the patient, duration of the infection, amount of the previous treatment, and symptomatology were omitted from the inquiry, further suggestions with regard to treatment are not possible. Occasionally patients are encountered who are sensitive to arsphenamine but who after a year's rest from treatment with it are able to tolerate the drug in small doses. The status of the syphilis and the need for drastic treatment are the factors that determine the need for further efforts at arsphenaminization in such cases.

SKIN CHANGES AFTER RADIUM TREATMENT

To the Editor:—A woman, aged 50, complains of much pain and discomfort at the site of x-ray and radium (?) treatment nine years ago for a goiter. The treatment was given both before and after thyroidectomy. She does not know whether it was malignant or not. The skin in this area is roughened, telangiectatic and adherent over the left sternomastoid muscle. No tumor is palpable. Various ointments have been used in order to make it feel more flexible and give relief to the pulling sensation and pain, but without relief. Any suggestion will be appreciated. Please omit name. M.D., Ontario.

ANSWER.—The palliative treatment of atrophy and telangiectasis of the skin following intensive x-ray or radium treatment is unsatisfactory. Avoidance of further irritation and the application of ointments constitute the only methods. Excision of the diseased skin followed by plastic repair must be considered. The decision as to the indications for surgery and the execution of the procedure are exceedingly difficult and should be entrusted only to one who is highly expert in this field. In the case cited, the location and extent of the lesion probably contraindicate surgery.

PSORIASIS OF FINGER NAILS

To the Editor:—I have a patient who has psoriasis of the finger nails. He has been to many skin specialists, receiving from time to time treatment containing salicylic acid for application to the nails, also light and x-ray treatments, and special diets. He has received best results from the x-ray and light treatments, but they require a long time and are very expensive. I should like to know whether you have any special treatment for this condition. I know it is chronic and it will take a long time before it heals. Kindly omit name. M.D., Pennsylvania.

ANSWER.—Psoriasis of the finger nails is much more resistant to therapy than psoriasis of the skin. The treatment employed is usually a modification of that used on the skin. The scraping of the nail with a glass slide to remove surface irregularities and debris, and the local application of an ointment is a most effective method of treatment. A 6 per cent salicylic acid and 6 per cent ammoniated mercury, or a 0.5 per cent dihydroxyanthranol ointment may then be rubbed into the nails. Roentgen therapy, while effective, must be used cautiously in order to obviate the occurrence of a radiodermatitis and other sequelae in the skin surrounding the nail. Restriction of fats and proteins in the diet has been recommended. The use of vitamin D and calcium by mouth, and the use of salicin, 1 Gm. in 30 cc. of peppermint water three times daily, is of value. Subcutaneous injections of sodium cacodylate, the use of sodium thiosulfate intravenously and the use of nonspecific therapy, such as whole milk intravenously, and autohemotherapy may be

further adjuncts to local therapy. In the latter procedure, 10 cc. of the patient's blood is given by intramuscular injection at intervals of from five to seven days.

MULTIPLE SCLEROSIS

To the Editor:—A white woman, aged 21, has a brother, aged 30, who has had multiple sclerosis for the past ten years. An incomplete and rather unsatisfactory cursory study of the family tree reveals no other neuropathic cases. Is marriage in her case advisable? How great are the possibilities of her or her children developing multiple sclerosis or another neuropathic condition at a later date? Kindly omit name. M.D., Kansas.

ANSWER.—The etiology of multiple sclerosis is unknown. Heredity may be an important factor. The latter is a congenital predisposition in the cerebrospinal axis which under certain situations becomes activated and the protean signs of multiple sclerosis develop. There are, however, many cases of multiple sclerosis occurring in one member of a family with no abnormalities of any kind in any of the other members. It is suggested that a complete study of the patient's family tree be made. If no other evidence of familial or hereditary disorders is found, the possibility of the patient's children having multiple sclerosis or other neuropathic states is unlikely.

COST OF SKIN DISINFECTANT SOLUTION

To the Editor:—In THE JOURNAL, February 13, page 577, you published a query and minor note entitled "Solution for Use as Skin Disinfectant." You state that the authors were able to prepare the formula given at \$1.60 a gallon, which is no doubt true, but you neglect to mention that they were using tax free alcohol. I have been preparing a similar formula for a customer but not at \$1.60 a gallon. I have to pay a tax (federal) of \$3.80 a gallon (wine) on nonbeverage alcohol, besides a state tax. WILLIAM H. BROOKE, Lincoln, Neb.

ANSWER.—The statement that the authors (J. A. Vaichulis and Lloyd Arnold, *Surg., Gynec. & Obst.* 61:333 [Sept.] 1935) were able to prepare the solution for \$1.60 a gallon is correct. They did so, however, working in the laboratories of a state university medical school and using tax free alcohol. With a federal tax of \$3.80 a wine gallon on nonbeverage alcohol, and in some states an additional state tax, obviously this solution could not be prepared at the price stated except in an educational institution where tax free alcohol is available.

TESTS FOR BLOOD SUGAR

To the Editor:—I wish to purchase a simple inexpensive outfit for estimation of blood sugar—one that can be used in my office and requiring only a few drops of blood, yet fairly accurate. The Epstein and also the Lamotte outfits have been recommended to me. Which is considered the better one—or do you know of one better than either of these two at about the same price? The Epstein is priced at \$17.50 and the Lamotte at \$24. J. STREET BREWER, M.D., Roseboro, N. C.

ANSWER.—Either of the instruments mentioned should prove quite satisfactory for the purpose. No other device of a similar nature should prove materially superior to these instruments.

The LaMotte equipment has greater flexibility and can be more easily expanded to accomplish a greater variety of work, but if used only for fairly accurate blood sugar determinations either should do very well.

EXCISION FOR PIGMENTED MOLES

To the Editor:—A girl, aged 15 years, has a number of brown (small) areas of pigmentation over her face. Some of them appear like soft, flat moles. What is the best way to remove them without too much scarification? Is removal by means of fulguration with the electric needle or electrocoagulation with the usual diathermy machine dangerous because of rendering the areas of pigmentation malignant? Please omit name and address. M.D., Maine.

ANSWER.—Presumably the lesions mentioned are pigmented moles. Most specialists believe that it is better to let such lesions alone or to remove them by excision. Electrodesiccation and electrocoagulation might fail to destroy all the cells, and these methods are likely to produce disfiguring scars.

ETIOLOGY OF TABES

To the Editor:—Is there a form of tabes that is nonsyphilitic? FELIX S. MARTIN, M.D., Beaumont, Texas.

ANSWER.—Tabes is always of syphilitic etiology. There are pseudotabetic syndromes caused by a number of other diseases that involve the posterior columns. However, tabes itself involves more than the posterior columns and is always syphilitic.

Book Notices

Artificial Pneumothorax: Experience of the London County Council. By F. J. Bentley. Medical Research Council, Special Report Series, No. 215. Paper. Price, 1s. 6d. Pp. 94, with 5 illustrations. London: His Majesty's Stationery Office, 1936.

Bentley has compared 677 persons treated by artificial pneumothorax with 3,329 treated by bed rest and other measures in the absence of collapse therapy. The average time over which artificial pneumothorax treatment was continued was 18.8 months, but of the patients alive at the end of the study the treatment had been continued over a period of approximately three years. Two hundred and sixty-six of the 677 patients treated by pneumothorax were followed for a minimum period of three years and 411 of the patients were followed for a period of five years, while the 3,329 treated without collapse therapy were followed for a period of five years. The 411 observed for five years showed a gain in the number alive of 19.8 per cent at the end of five years over those treated conservatively. Of the total 677 treated by artificial pneumothorax, in 267 the collapse was incomplete and of this number only 50 per cent were alive at the end of three years. Of the remaining 208 patients with complete collapse 65.9 per cent were alive after three years, while among those who had only unilateral disease 77.4 per cent were alive at the end of three years. Of those who survived in this pneumothorax group, 64 per cent had quiescent disease after five years while only 38 per cent of those treated conservatively were in this stage at the end of five years. The author points out that there is also a definite increase in the working capacity in the pneumothorax group. He observed that the longer disease exists the more likely it is to involve both lungs and the greater the chances of adhesions developing which prevent complete collapse. He is of the opinion that it is unwise to wait too long before instituting artificial pneumothorax and that when the disease is unilateral and tubercle bacilli are found in the sputum the treatment should be considered at once. He is cognizant of the fact that some such patients will control their disease but that too frequently without artificial pneumothorax it tends to advance. He also calls attention to the fact that, if the disease is brought under control without collapse therapy, among those who must do manual work there is an "awful risk" of reactivation within two or three years. Moreover, in patients who do break down by the time treatment is instituted for the second time the disease is usually too advanced for any kind of therapy to be of avail. Bentley states that in 1934 only approximately 10 per cent of the patients being treated for pulmonary tuberculosis were on artificial pneumothorax treatment. He does not believe that this percentage will be definitely increased because of the lack of suitable cases admitted to the institutions. In spite of a review of the literature, he bases his statement on the observation of hospital cases alone, ignoring the case-finding methods now in practice in many sections with its resultant increase in suitable cases for artificial pneumothorax and ambulatory pneumothorax for the early case. However, this study shows that artificial pneumothorax even in the type of case observed by Bentley is decidedly worth while, since 19.8 per cent more so treated survive than among those who are treated by institutional care alone. Its importance lies in further evidence from a hitherto unreported section that pneumothorax constitutes the most valuable single treatment of tuberculosis now extant.

Christian B. Holmes, Man and Physician. By Martin Fischer. Cloth. Price, \$4. Pp. 233, with illustrations. Springfield, Illinois, & Baltimore: Charles C. Thomas, 1937.

Here in a beautiful volume as artistically written as it is beautifully printed, Martin Fischer tells the story of the life of Christian Holmes of Cincinnati. The book is not likely to command a tremendous audience and it has the personal qualities that are certain to make it appeal to the audience that was personally interested in Holmes and his accomplishments.

In 1885 Christian Holmes came to the Cincinnati Hospital. From that time on his entire life was devoted primarily to its interests. He was to rebuild it and eventually to make it the great institution which it is today. The life of Christian Holmes is intimately bound also with the story of the Fleischmann

family. The history of all our great institutions is largely the history of the men who live for them. This is particularly true of the medical institutions of Cincinnati. The life of Christian Holmes, as narrated by Martin Fischer, traces the intricate web of politics and financing that was created to meet successfully the conditions that existed. As in other instances, the creation of the institution is only the beginning. Thereafter come the questions of maintenance. It is not sufficient merely to set up certain standards. Thereafter comes the battle against those without ideals who continually attempt to break down standards. These conflicts and struggles made the life of Christian Holmes particularly dramatic. He had frequent opportunities to abandon his projects in Cincinnati for a new career elsewhere, many times perhaps even a greater one; but he preferred to undergo the exactions and vicissitudes of his chosen home. His story includes the building not only of hospitals but also of the medical school and then a successful marriage of the two organizations into a great service and teaching institution.

An exceedingly interesting feature of this remarkable volume are the side-headings on the individual pages, which are aphorisms from the great literature of the world reflecting on the career of the remarkable man whom the book concerns. The volume will be read with interest by every one who has followed the course of medical education and medical development in the United States during the particularly active last quarter century.

L'ostéosynthèse au point de vue biologique: Influence de la nature du métal (étude expérimentale). Par G. Menegaux, chirurgien des hôpitaux de Paris, et D. Odiette, assistant à l'Institut de cancer. Préface du Professeur J. Verne. Paper. Price, 35 francs. Pp. 175, with 71 illustrations. Paris: Masson & Cie, 1936.

For more than two years Menegaux and Odiette have been studying the reaction of bone to various metals, from the biologic point of view, because they have found that rarefying osteitis, subsequent pathologic fracture, and other clinical failures resulted from the use of metal fixation devices in fractures. After performing more than two thousand tissue culture experiments and more than a hundred operations on animals, they feel qualified to declare which metals are desirable for use in bone.

Tissue cultures of fibroblasts and osteoblasts from the chick embryo and fibroblasts from the human embryo (cases of extra-uterine pregnancy) were subjected to the effects of forty different metals and alloys. Careful microscopic studies of the cultures and quantitative analyses were made. In the animal experiments, metal disks were placed under the periosteum, wire loops were placed in and around the bone, and Lane plates and screws of different metals were applied.

The results of these detailed studies lead the authors to state that iron, steel, bronze-aluminum, copper and magnesium have a very toxic effect on bone. They are therefore condemned as unfavorable for bone surgery. If, however, their use is unavoidable they should be removed as soon as they have served their function. Most of the pure metals, the alloys of aluminum, and most stainless steels are moderately toxic in their action on bone. The nontoxic metals are gold, lead and aluminum (all of which are soft in their pure state and not practical to use), and three of the stainless steels (V2A Extra, Nicral D and Platino-Stainless D). The authors condemn plated metal appliances, moreover, because the plating might crack and permit the exposure of the iron or steel base, which is toxic.

The authors discuss the possibility that when two metals are used in the same bone there may be some electrolytic reaction which would be inhibitory to bone growth. However, in none of their experiments could they prove this and they dismiss it as a negligible factor. This is contradictory to the observations of Venable, Beach and Stuck in this country, who have recently demonstrated that the use of appliances of different metals in the same bone induces electrolytic reactions that are destructive to bone.

Despite their extreme care and thoroughness, Menegaux and Odiette have simply repeated the experimental approach and reemphasized essentially the same conclusions as many previous workers in this field. A distinct contribution, however, is the description of a method for growing osteoblasts in hanging

drops wherein the growing cells can be clearly observed and studied experimentally. The book is illustrated with excellent photomicrographs, which are well titled and readily demonstrate the points the authors seek to establish.

Pharmacognosy. By Edmund N. Gathercoal, Ph.G., Ph.M., Professor of Pharmacognosy, University of Illinois College of Pharmacy, and Elmer H. Wirth, Ph.C., Ph.D., Assistant Professor of Pharmacognosy, University of Illinois College of Pharmacy. Cloth. Price, \$7.50. Pp. 852, with 373 illustrations. Philadelphia: Lea & Febiger, 1936.

Pharmacognosy means "the entire knowledge of drugs." Modern pharmacognosy, however, does not include medicinal or pharmacologic action. The drugs discussed in this book are limited to those of plant and animal origin. Synthetics and inorganic drugs, if mentioned at all, are incidental; official chemical substances, however, obtained from crude drugs get considerable attention. The Greek Herbal of Dioscorides (A. D. 512) may be considered the first textbook of pharmacognosy and Dioscorides a teacher of pharmacognosy. In fourteen centuries much water has run over the pharmacognosy mill, and naturally great advances have been made. Up to the seventeenth century the best books on medical botany were still commentaries on the Herbal, which was also the historic source of much of our therapy. Its descriptions were of the gross specimens; today the emphasis is on microscopic structure and chemical, biologic and physical tests. The authors give a list of thirty or more important books on the subject with due credit. It is this scientific spirit, combined with clarity, completeness and modernity, that bespeaks a wide adoption of the book. Pharmacognosy today demands a knowledge of botany, zoology, bacteriology, chemistry, physics and crystallography. The book emphasizes these sciences as applied to pharmacognosy. It is the very extent of these subjects that has restricted the teaching of pharmacognosy in the medical schools. Important in the medical curriculum for centuries, pharmacognosy now receives scant recognition, not because it is underestimated as a scientific discipline but because other subjects of more pressing need have supplanted it. There are, however, times when questions arise in practice, where the physician will want more information on a drug than is given in the Pharmacopoeia, and where this book will furnish the information in a reliable and concise form. Such modern therapeutic agents as vitamins, vaccines and bacteriologic products are discussed. For students of pharmacognosy we know no better book. The style is clear; the descriptions are concise and accurate. The numerous illustrations are excellent. Physicians and general scientists interested in subjects beyond their special fields will find it a valuable source of information. Laboratory workers in pharmacology, chemistry and food and drug inspection work will find it a good reference book.

The Queen Charlotte's Text-Book of Obstetrics. By Trevor B. Davies, M.D., F.R.C.S., F.C.O.G., Gynecological Surgeon, Hospital for Women, Soho, and others. Fourth edition. Cloth. Price, 18s. Pp. 674, with 295 illustrations. London: J. & A. Churchill, Ltd., 1936.

This book, like the three previous editions, was written by the active staff members of the Queen Charlotte's Maternity Hospital. A number of changes and improvements have been made particularly in the chapters dealing with puerperal infection. This is because during the last few years important contributions have been made to the subject of puerperal infection by Leonard Colebrook in the Queen Charlotte's Research Laboratories. The authors have altered their treatment of eclampsia, for they have given up the use of colon lavage, sweating and veratrine. In a series of 841 cases of placenta praevia there were no deaths among the 116 patients who delivered spontaneously, one death among sixty-one cesarean section (1.6 per cent), and much higher maternal death rates for the other forms of delivery. In reviews of two previous editions of this book, it was pointed out that illustrations were reproduced or copied from DeLee's textbook but that no mention was made of this fact. In the present edition proper credit is given to DeLee for the illustrations that were taken from his book. In 1930 an isolation block was opened for the study and treatment of puerperal sepsis. In this block it has been found that 19 per cent of the patients transferred because of fever from the wards of the main hospital showed an infection due to *Streptococcus haemolyticus*, whereas 60 per cent of the women transferred from the district had an infection due to this organism. This is contrary to the generally accepted

view that the incidence of potential serious infection is greater among women delivered in hospitals than among those delivered in their own homes. In the third edition the authors quoted Kerr and Holland's statistics, which were published in 1921 and which showed a death rate of 7 per cent for 4,160 classic cesarean sections, as contrasted with a mortality of 15 per cent for thirty-three lower segment operations. It is unfortunate that the authors repeat these fifteen year old statistics in the fourth edition, especially because the thirty-three cervical operations represented the first crude efforts of a few British obstetricians. In spite of the poor showing of the cervical operations in 1921, one of the authors of the 1921 report (Kerr) is today the greatest advocate of the low cervical operation in the British Isles. Furthermore, world-wide statistics prove the superiority of the cervical cesarean section over the classic operation. This book ranks among the best in Great Britain, and the appearance of a fourth edition within nine years attests its great popularity.

Principles of Chemistry: An Introductory Textbook of Inorganic, Organic and Physiological Chemistry for Nurses and Students of Home Economics and Applied Chemistry, with Laboratory Experiments. By Joseph H. Roe, Ph.D., Professor of Biochemistry, School of Medicine, George Washington University. Fourth edition. Cloth. Price, \$2.75. Pp. 475, with 41 illustrations. St. Louis: C. V. Mosby Company, 1936.

This is intended to be a combined textbook and laboratory manual for the chemistry, inorganic, organic and physiologic, taught in nurses' training courses and in some home economic courses. It is strictly up to date and well written. In a textbook designed for courses in which the amount of time for the study of chemistry is very limited, much of the value of the text depends on the wisdom of the author in choosing what subjects to include and what to leave out. Quite naturally, the treatment of the inorganic part of the text is the largest because in this part the introductory subjects, which include chemical laws, solutions, equations, units of measure and the like, are treated. However, this part of the text is not complete enough for an ordinary freshman course in chemistry. The organic and physiologic portion of the text are combined. The portion dealing with pure organic chemistry is abbreviated: that dealing with such subjects as metabolism, nutrition, elimination, hormones and vitamins is given somewhat longer treatment. This portion of the text, more than the former, relates to what are considered facts instead of the reasons for the facts. It is convenient for the student to have a laboratory manual combined with the text. In the laboratory manual portion of this volume there are blank pages for notes. Students who would use this book need instruction and outlines for writing up experiments, in order to classify in their own minds what they have done, what they have observed and what they have concluded. If these blank pages are used for taking notes in the laboratory they will be helpful; if they are used as the one and only laboratory notebook, an exceptional laboratory teacher will be required to get more than a hodgepodge.

Geschichte der physiologischen Chemie. Von Dr. Fritz Lieben, Privatdozent an der Universität Wien. Paper. Price, 20 marks. Pp. 743. Leipzig and Vienna: Franz Deuticke, 1935.

The history of physiologic chemistry is presented in two main sections and from two different points of view. In the first part are the usual historical development of chemistry—the chemistry of the ancients, the iatrochemical and phlogiston periods, and then chapters on Lavoisier to Berzelius, Liebig and his contemporaries in Germany, the great French chemists of the nineteenth century and the great German chemists of the nineteenth century. Unfortunately, the sources for the periods prior to the nineteenth century are the usual histories of chemistry. It would seem that more use of original ancient, medieval and eighteenth century literature would have opened up many household, agricultural, medical and industrial practices, customs and superstitions of special biochemical interest in the light of present knowledge. The second part is not so much a history of the science as a chronologically arranged descriptive treatment of twelve special subdivisions of biochemistry. These chapters cover nutrition, vitamins and metabolism; muscle chemistry, metabolism and dynamics; protein chemistry and metabolism; fermentations; the oxygen-carrying property of the blood; bile composition and function; lipins and their metabolism; carbohydrates and their metabolism; nucleic acid

chemistry and metabolism; the composition of urine and the significance of the results; inorganic constituents and their needs in living matter, and hormones. Each in turn is treated briefly with respect to the ancient and medieval views and at greater length their development since the time of Lavoisier. Each chapter closes with a statement of the main sources of the material presented. Curiously, nothing is stated as to the development of the physical-chemical aspects, the importance of special analytic methods, concepts and tools, and the absolute necessity of the micro methods of Pregl for the developments in vitamins and endocrine principles. The work includes good author and subject indexes. It is a valuable reference work for every teacher of biochemistry from the standpoint of historical development, although one might have desired more information on the erroneous views of the earliest and later centuries and the reasons and difficulties involved.

A Synopsis of Surgical Anatomy. By Alexander Lee McGregor, M.Ch., F.R.C.S., Lecturer on Surgical Anatomy, University of the Witwatersrand. With a foreword by Sir Harold J. Stiles, K.B.E., F.R.C.S. Third edition. Cloth. Price, \$6. Pp. 664, with 648 illustrations. Baltimore: William Wood & Company, 1936.

This textbook is written with the object of presenting valuable facts to the senior student and practitioner. It consists of two parts: the anatomy of the normal and the anatomy of the abnormal. In the first part surgical anatomy is considered with reference to the various regions of the body. The head, neck, chest, abdomen and pelvis with their contents are taken up, followed by the vertebra and the bones of the extremities. In each region the various nerves, muscles, blood vessels and lymphatics are considered with reference to their surgical importance. In the second part the same systematic plan is followed with a discussion of the surgical conditions that may result from developmental and abnormal anatomic errors. The omission of all but the essential points makes their surgical importance clear in a few brief sentences. The anatomic basis and description of certain clinical tests and the anatomic advantages of certain operations is included, making the text more interesting to the student and the clinician. There are 648 simple line diagrammatic drawings to illustrate a text of 623 pages. These are particularly designed to permit one to see almost at a glance the normal and abnormal anatomic points of interest. The book is not only a most instructive synopsis of anatomy but is carefully planned to promote its practical application to clinical diagnosis and operative surgery.

Mind, Medicine and Metaphysics: The Philosophy of a Physician. By William Brown, D.M., D.Sc., F.R.C.P. Cloth. Price, \$3. Pp. 294. New York & London: Oxford University Press, 1936.

This is a collection of essays and lectures dealing with psychologic, philosophic, and religious aspects of medicine. The author is a physician, a psychologist and a philosopher, holding official positions in each of these capacities. Just as versatility is said to be the curse of genius, so this diversity of interests seems to have impaired the author's ability to take a pronounced stand with respect to any of them. He commends psychoanalysis with reservations; he takes the Oxford movement seriously enough to point out some of its obvious psychologic faults; he reports the case of a hypnotic trance in a medium controlled with a psychogalvanometer. He discusses the psychology of international relations, the sexual problems of adolescents, the relation of religion to psychology. Whether or not one shares the author's views about many of these things, there is little fault to find with what he says; it is rather that his restraint, his feeling that he must not go too far in commending or criticizing anything, his relatively superficial and often repetitious treatment of this wide variety of topics makes the book rather undistinguished. It cannot be said to represent anything except the philosophic ruminations of a widely read scientist with religious inclinations. His criticism of the Oxford movement would indicate that this is taken more seriously in the country of its origin than in the United States. The author shows that from the psychologic standpoint its techniques are neither valid nor adequate as devices for consistently altering personalities, but, having rather carefully demonstrated this fact, he ends by "hoping" that he has not been unnecessarily critical and that "the movement itself may become deepened as it goes on and that the conversions . . . will become consolidated by deep religious development. . . ."

Experimental Physiology with Anatomical and Mechanical Illustrations and an Appendix of Technical Data. By Maurice B. Visscher, Ph.D., M.D., Professor of Physiology and Head of the Department in the University of Illinois, Chicago, and Paul W. Smith, Ph.D., Associate in Physiology in the University of Illinois. Cloth. Price, \$3.25. Pp. 191, with 75 illustrations. Philadelphia: Lea & Febiger, 1935.

The experiments described in this laboratory manual are obviously adapted to the equipment and conditions of the authors' laboratory but most of them are readily adaptable to any equipment. One especially valuable feature of the book is the extensive use of new and original illustrations of apparatus and operative procedures. Another is the appendix of twenty pages, in which are found directions for the preparation of special solutions, dosages of drugs commonly used in laboratory work, formulas and other general information. There are 113 experiments listed, some of which are adaptations of classic experiments, others of original design. In their efforts to "modernize" some of those in the first group the authors appear to have overdone the job to some extent, as the revisions have neither added to the illustrative value of the experiments nor clarified the description of the procedures involved. Also there are some poorly advised efforts to apply physicochemical principles, such as the calculation of the osmotic pressure of plasma proteins on page 24. Any one acquainted with the principle of the Donnan equation is aware that the conditions of the experiment as described cannot provide the exactitude that is implied. The experiment would make a better impression on the student if the calculation were omitted entirely. This criticism applies as well to the calculation of the osmotic work of the kidney outlined on page 164. There are many other experiments more suitable for the purpose. However, individual instructors may omit requirement of these calculations if they desire and may still find the manual of value as a laboratory guide for students of any grade.

Official and Tentative Methods of Analysis of the Association of Official Agricultural Chemists. Editorial Board: W. W. Skinner, Chairman. Committee on Editing Methods of Analysis: E. M. Bailey (Chairman), and others. Fourth edition, 1935. Cloth. Price, \$5; for 5 or more copies, \$4, each. Pp. 710, with 52 illustrations. Washington, D. C.: Association of Official Agricultural Chemists, 1936.

This issue is presented in accordance with the original plan to publish a revision every five years. The aim of the work is to include all the approved methods of the association for the analysis of agricultural products and of related substances. The procedures are given in clear, concise statements with no typical analyses. The noteworthy feature is the clarity of composition. The subject matter and arrangement closely resemble those of the third edition. A few unsatisfactory or unimportant methods have been omitted, while other chapters, such as that on beers, wines and distilled liquors, have been expanded. One chapter, "Nuts and Nut Products," which was mentioned in the third edition for future inclusion, has been added. Six other subjects are still being contemplated. Appendix I, dealing with preparation and standardization of solutions, is a valuable addition. The book is an authoritative analytic guide but is not a great improvement over the preceding edition.

La diphtérie. Par G. Carrière, professeur de clinique médicale à la Faculté de médecine de l'Université de Lille. Paper. Price, 35 francs. Pp. 213, with 45 illustrations. Paris: Masson & Cie, 1936.

In the present day a treatise on diphtheria is not likely to attract wide attention. The literature is voluminous and the average physician undoubtedly feels that he has a satisfactory knowledge of the disease. Carrière, however, has presented the subject in a remarkably complete and concise manner. One can readily appreciate when reading this book that the author's thirty-five years' experience has permitted him to discuss phases of diphtheria which are not mentioned in the average textbook. The gravity of diphtheria when associated with streptococcal infection receives comment. It is also asserted that measles and scarlet fever lessen immunity to diphtheria. The author has observed tracheobronchial diphtheria only three times in a period of thirty years but states that bronchopneumonia was noted in four fifths of the necropsies (diphtheria) in infantile clinics from 1900 to 1925. Saturation of the atmosphere about diphtheria patients with antiseptic vapors is recommended. With regard to dosage of diphtheria antitoxin, it is stated that "500 units per kilo of weight is curative, necessary and suf-

ficient." Tests for sensitivity are always made from four to five hours before injection of antitoxin. Some of the author's views with respect to treatment would in all probability not be acceptable to most clinicians in this country. The value of antiseptic vapors about the patient seems doubtful and the weight method of determining dosage of antitoxin unsatisfactory. The book is divided into twenty-four chapters. There are a number of illustrations, including three plates in color; also graphs and tables. It is well worth reading and will prove of value to any one interested in the subject.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Workmen's Compensation Acts: Liability for Fee of Physician Not Authorized to Treat Compensation Cases.

—The legislature of New York, in 1935, amended the workmen's compensation act to give to an injured employee, except under certain enumerated conditions, the right to select the physician to treat him, such selection to be made from a panel of physicians specially authorized to treat compensation cases in the following manner:

The commissioner shall upon the recommendation of the medical society of each county or of a board designated by such county society, or by a board representing duly licensed physicians of any other school of medical practice, authorize physicians licensed to practice medicine in the state of New York to render medical care under this chapter. If, within sixty days after the commissioner requests such recommendations, the medical society of any county or board fails to act, or if there is no such society in the county, the commissioner shall designate a board of three qualified physicians, who shall make the requested recommendations.

No physician not so authorized by the industrial commissioner may collect any fee for treatment rendered to compensation patients. The plaintiff, a physician, treated an injured employee, apparently at the request of the employer. He thereafter brought suit against the employer in the supreme court, special term, New York County, to enforce payment of his bill. In his complaint, however, he did not allege that he had been duly authorized to render medical care under the workmen's compensation act. The sole question before the court was whether the failure to include such an allegation in the complaint rendered it defective so as to entitle the employer to a dismissal of the case.

Prior to 1935, the court said, while the workmen's compensation act provided for medical care and treatment of injured employees, there was scant provision regulating the rendering of such treatment. The guiding principle was that the employer was to provide medical care, and he it was who in the ordinary case chose the physician. The industrial board had no jurisdiction to make an award for hospital bills or physicians' services except in two cases: (1) where the employee requested his employer to furnish medical treatment and the employer neglected or refused to do so, and (2) where the nature of the injury required such treatment and the employer or his superintendent or foreman, having knowledge of such injury, neglected to provide the treatment. In other cases the employer became directly obligated to the physician, who had his remedy in the courts and not under the workmen's compensation act. Protests arose from various sources against abuses that had grown up involving the medical care of injured workmen. A joint committee of the Medical Society of the State of New York and the Academy of Medicine was appointed to study the situation and a report by this committee was made the subject of a special message by the governor to the legislature. As a result the act was amended in 1935. One purpose of the particular amendment under discussion, said the court, was to restrict the treatment of all compensation cases to physicians authorized by the industrial commissioner to render such treatment. Permitting the employee to select his physician is, the court emphasized, a salutary step, since it was the absence of such right that gave rise to so many abuses under the old law. Whether the physician is chosen by the employee or

under certain enumerated conditions, by the employer, one thing is implicit in the amended act, the physician must be one authorized to render medical treatment in workmen's compensation cases. To hold that an employee must select a physician duly authorized under the act, and, if the choice be one which the employer may exercise, to permit him to select any physician whether authorized to render services under the act or not, would lead to unjust results. If the plaintiff in the present action, the court said, is entitled to judgment the desirable benefits of the 1935 amendments to the compensation act will be to a large extent nullified. Any unauthorized physician would then be entitled to bargain with employers for the treatment of injured employees. Whenever the employee does not object, and in many cases through pressure from the employer or through ignorance of the law he will not object, such unauthorized physicians would be in a position to provide medical care for fees at variance with the prescribed schedules of minimum fees and without being subject to the disciplinary provisions of the amended act. The door would then be open to a revival of the very abuses which the amended act was intended to cure, the cut-throat competition and commercialization of compensation medical practice, the improper "lifting" of cases and the inadequate and inefficient treatment of injured workers.

While the practice of medicine is a property right, it is one which is subject to the most stringent regulations. The right to practice medicine must yield to the paramount right of the state to protect health by any rational means. A state may not only impose requirements prerequisite to a license to practice medicine generally, but it may impose additional requirements as a condition to permitting a licensed physician to continue to practice and to treat employees under the workmen's compensation act. The right to practice medicine is not essentially different from the right to practice law. The fees of attorneys in compensation cases have been strictly limited and the courts have upheld those limitations. The requirement that only authorized physicians treat compensation cases bears a reasonable relationship to the orderly and efficient administration of the act. In concluding, the court summarized its holding as follows:

(1) That the Legislature has power to abrogate in whole or in part the common-law rights of physicians who treat workmen's compensation cases. By that I mean, for example, that the Legislature has power to provide that a physician's exclusive remedy to recover payment for treating compensation cases shall be under the Workmen's Compensation Law and not in the courts; that it may by reasonable provisions restrict and limit the contractual relations between physicians on the one hand and employers or injured employees on the other, and that such reasonable restrictions may be made applicable not alone to the awards to physicians under the Workmen's Compensation Law, but to actions for services in the courts as well;

(2) The requirement that only physicians who are specially authorized by the Industrial Commissioner for that purpose may treat injured employees in accordance with the provisions of the Workmen's Compensation Law is a reasonable one, calculated to accomplish the humane objects of that statute and to do away with abuses and evil practices that arose in connection with its administration;

(3) No physician under the amended statute is permitted to treat compensation cases or entitled to be paid therefor unless he is authorized by the Industrial Commissioner, and this applies whether the physician is chosen by the employee or by the employer;

(4) Assuming but not deciding that a physician chosen by an employer to treat a compensation case may, despite the amended statute, sue the employer in the courts for payment of his services, as a condition to recovery he is required to allege and prove that he was duly "authorized" to render medical care to injured employees under the Workmen's Compensation Law.

For the reasons stated, the court granted the motion made by the employer to dismiss the complaint.—*Sold v. Outlet Embroidery Supply Co., Inc.* (N. Y.), 289 N. Y. S. 411.

Paternity: Determination by Blood Grouping Tests.—The defendant was convicted on a charge of fornication and bastardy. He appealed to the superior court of Pennsylvania contending, among other things, that the trial court erred in refusing to require the prosecutrix to submit herself and her baby for a blood grouping test to determine the paternity of the baby, and in refusing to continue the trial of the case pending the taking of such tests.

It was not an abuse of discretion, said the superior court, for the trial court to refuse to continue the case after the jury had been sworn. Furthermore, even had the petition been

presented earlier it would have been the duty of the trial court to refuse the motion. At common law, the defendant did not have a right to a physical examination of the plaintiff in an action for personal injuries. In personal injury cases in which the amount of damages to which a plaintiff is entitled is at issue, the rule in Pennsylvania is that it is within the discretion of the trial court to require the person injured to submit to a physical examination for the purpose of determining the extent of the injury. The exercise of such power, however, is a matter within the discretion of the trial court and only subject to appeal when such discretion is abused. But, said the court, we are here concerned not with a civil but a criminal case in which the commonwealth is the plaintiff. To refuse to permit a criminal case to proceed until a recalcitrant witness submits to an examination would deprive the commonwealth of its right and duty to enforce the criminal laws. In addition, the granting of the prayer of the defendant's petition would result in more than a mere permission to inspect the body of the prosecutrix, for it was proposed to insert a needle in her body and withdraw a small amount of blood for an examination. While such an operation is not regarded as entailing any serious danger to health, it cannot be said that there is no danger, for there is always present some risk of infection. Furthermore, the record in the present case, the court said, was entirely void of proof as to the scientific accuracy of blood grouping tests and such tests have not attained such standing as to justify a court in taking judicial notice of their value. Until the legislature finds that blood grouping tests have attained such scientific standing as to possess probative value as to paternity, the courts have not the power in a criminal case such as the one here involved to compel a prosecutrix to submit her body for blood tests.

While holding that the trial court ruled correctly with respect to the matter of blood grouping tests, the superior court felt impelled to reverse the judgment of conviction for other reasons and remanded the case for a new trial.—*Commonwealth v. English (Pa.)*, 186 A. 298.

Workmen's Compensation Acts: Compensability of Tuberculosis.—The workmen's compensation act of Connecticut defines a personal injury for which compensation may be allowed as including only an "accidental injury which may be definitely located as to the time when and the place where the accident occurred, and occupational disease." An occupational disease is defined as "a disease peculiar to the occupation in which the employee was engaged and due to causes in excess of the ordinary hazards of employment as such." The claimant contracted tuberculosis in the course of her employment by the defendants, manufacturers of women's dresses. The compensation commission awarded the claimant compensation under the workmen's compensation act, the superior court reversed that award, and the claimant appealed to the Supreme Court of Errors of Connecticut.

To constitute an occupational disease within the meaning of the workmen's compensation act, said the court, the disease must be a natural incident of a particular kind of employment, one which is likely to result from that employment because of its inherent nature. The act does not embrace a disease which results from the peculiar conditions surrounding the employment in a type of work which would not from its nature be more likely to cause the disease than would other kinds of employment carried on under the same conditions. Thus, pneumoconiosis resulting from wet grinding is an occupational disease. *Rousu v. Collins Co.*, 114 Conn. 24, 157 A. 264. Pneumonia, however, resulting from exposure incurred in highway construction is not. *Galluzzo v. State*, 111 Conn. 188, 149 A. 778. In the present case, the claimant's disease resulted from the conditions of her particular employment in the factory. Other trades, however, carried on under those conditions would have been as likely to cause the disease as the manufacture of dresses. To award compensation to the claimant, therefore, would be in contravention of the legislative intent as embodied in the workmen's compensation act. The case of the claimant evoked the sympathy of the court, for the record disclosed that the tuberculosis from which she suffered was contracted because of conditions of employment

which never should have been permitted to exist. But if such cases, the court said, are to be brought within the act, the legislature must do it. The judgment of the superior court remanding the case with instructions to dismiss the claim was therefore affirmed.—*Madeo v. I. Dibner & Bro., Inc. (Conn.)*, 186 A. 616.

Society Proceedings

COMING MEETINGS

- American Medical Association, Atlantic City, N. J., June 7-11. Dr. Olin West, 535 North Dearborn St., Chicago, Secretary.
- American Academy of Pediatrics, New York, June 3-5. Dr. Clifford G. Grulee, 636 Church St., Evanston, Ill., Secretary.
- American Academy of Tuberculosis Physicians, Atlantic City, N. J., June 7-8. Dr. Arnold Minnig, 638 Metropolitan Bldg., Denver, Secretary.
- American Association for the Study and Control of Rheumatic Diseases, Atlantic City, N. J., June 7. Dr. Loring T. Swaim, 372 Marlborough St., Boston, Secretary.
- American Association for the Study of Goiter, Detroit, June 14-16. Dr. W. Blair Mosser, 133 Biddle St., Kane, Pa., Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

- Relative Biologic Effectiveness of Fast Neutrons and X-Rays on Different Organisms. R. E. Zirkle, Philadelphia; P. C. Aehersold and E. R. Dempster, Berkeley, Calif.—p. 556.

Multiple Glomic Tumors.—Bergstrand describes two cases of multiple glomic tumors localized in the posterior lateral part of the foot, in the malleolar region. In one case six tumors were observed. One of these lay deeply within the adipose tissue in the sinus tarsi. In the second case there was a subcutaneous tumor and tumors in the calcaneus, talus, os cuboideum and the fifth os metatarsale, a localization heretofore unknown. In one of the two cases of multiple glomic tumors previously described in the literature, the tumors were also localized in the heel.

Studies in Genetics of Human Neoplasms.—In 1932 Martynova began a systematic study on the genetics of human tumors. Cancer of the breast was studied first because of its comparative ease of diagnosis. In all, 201 female patients were examined and their pedigrees obtained. The material was definitely not a collection of familial cases. Altogether the 201 pedigrees included 7,173 persons. In the study of the genetics of cancer of the breast two problems present themselves: general predisposition of the organism to cancer and local predisposition to cancer of the breast. In an attempt to obtain a solution of these problems, the frequency of cancer was compared with the incidence in the general population. The percentage of cancer among relatives of the series under discussion was much higher than in the control population of the same age, or among relatives of leukemia patients. This high familial incidence of cancer for all categories of relatives speaks against its chance occurrence and indicates that hereditary factors play a definite part in the etiology of the disease. A comparatively high percentage of uncles and aunts were affected, as compared to parents. This is best explained by the fact that the patient is generally better informed concerning those of his relatives having the disease than those that are healthy. Cancer of the breast is more frequent in all categories of female relatives of the patients than in the control population.

The disease was eighteen times as frequent in mothers of patients as in mothers of similar age in the control group. These facts indicate an inherited predisposition to cancer of the breast. This conclusion is further substantiated by the fact that cancer of the breast in women is generally fourth or fifth in frequency, following cancer of the stomach, uterus, esophagus and liver (including gallbladder). The author's data indicate that there is a hereditary predisposition to cancer of the breast as well as to cancer in general. It seems that there is complete absence of inbreeding among the relatives of the patients. The percentage of cases of cancer of the breast is much higher in mothers than in sisters of patients. Age may be an important factor here, but it is doubtful whether this alone can account for the difference. As regards general predisposition to cancer, there were six instances in which both parents had cancer—in two cases cancer of the same organ—and all the offspring resulting from these marriages were unaffected, though seven of these were more than 40 years of age, making it very unlikely that general predisposition to cancer is determined by a recessive gene substitution. It is possible that some of these offspring may yet develop the disease, although it is hardly likely that all will do so. It is more probable, therefore, that one has to do with a dominant form of inheritance. The degree of expression of the genetic factors involved cannot yet be evaluated, and it does not follow that these observations for cancer of the breast are necessarily true for other forms of cancer. Among the relatives of the patients in the series, fifty-one had tumors other than cancer, there were twenty-three instances of benign growths of known diagnosis, and twenty-eight cases were indicative of a benign neoplasm.

Urine Studies After Administration of Aminoacetic Acid.—Adams and her colleagues determined the composition of urine collected at hourly intervals for from four to five hours after the ingestion of aminoacetic acid (from 10 to 20 Gm.) for normal individuals and for patients who had myasthenia gravis, progressive muscular dystrophy or fatigability of indefinite origin. The response of the individuals in these groups was qualitatively similar. In addition to the increased elimination of urea, uric acid and amino acids to be expected, there usually occurs an increased excretion of creatine. This may be slight or nonexistent the first time aminoacetic acid is given. If a creatinuria already exists, however, or has been provoked by the daily administration of aminoacetic acid, the prevailing hourly rate of excretion of creatine will in general be increased markedly when aminoacetic

acid is taken, either for the first time or immediately following the regular daily dose. The experiments were conducted from fourteen to sixteen hours after the last meal; consequently the results may be taken to represent the effects of aminoacetic acid more simply and more directly than the results of studies of twenty-four hour specimens of urine obtained from subjects who are receiving their usual diet. The hourly excretion of the sulfur partition products and the inorganic constituents was not influenced consistently by the administration of aminoacetic acid.

Death Complicating Withdrawal of Narcotics.—During three years Piker and Gelperin have seen three deaths in narcotic addicts who had been suddenly deprived of the drugs to which they had become habituated. The principal clinical manifestations common to all three were coma, an unusual respiratory disturbance and death. The respiration was irregular and uniformly deep. Periods of apnea of varying lengths (up to one and one-half minutes) occurred at irregular intervals, to be followed immediately by deep, gasping inspirations during which all the accessory muscles of respiration were put to vigorous use. The expiratory phases were not particularly forceful. Generalized cyanosis was marked. These dyspneic periods fluctuated in duration in the same patient, lasting from five minutes to several hours. During the intervals between the attacks of dyspnea, which also varied in length, the cyanosis diminished. The administration of morphine sulfate subcutaneously had no appreciable effect. Though the respiration suggested the Cheyne-Stokes type of breathing in some respects, it was by no means typical. Gross and histologic study of the medulla on postmortem examination in one of these cases revealed no enlightening pathologic condition. It is known

that the depressing effect of a poisonous dose of morphine on the respiratory center of the frog will eventually result in a type of respiration which is somewhat like that seen in the authors' patients. This fact, however, does not explain why abrupt withdrawal of the poisonous substance should produce a similar result. The unusual respiratory behavior was common to all three patients despite the existence in each case of factors which made it distinct from the others. The type of opium derivative to which each was habituated, the time between the patient's last dose of drug and the onset of coma and respiratory difficulty, the non-narcotic medication given before and after the onset of the coma—these and other factors varied markedly in the three cases. The circulatory failure did not occur in two of the patients (save as a terminal phenomenon).

Night Blindness as Criterion of Vitamin A Deficiency.—Jeghers discusses the prevalence of vitamin A deficiency in a group of supposedly normal adults, gives some preliminary results obtained by testing persons afflicted with various types of diseases, and reviews the literature dealing with the physiology, biochemistry, pathology and clinical aspects of vitamin A deficiency. Night blindness (hemeralopia), in the absence of intra-ocular disease, is the earliest and most constant manifestation of vitamin A deficiency in adults. In adults, night blindness may exist for years as its only manifestation. Night blindness is associated with certain objective data which can be measured by means of special procedures. These serve as a quantitative estimate of the degrees of vitamin A deficiency and are particularly valuable in that they can detect deficiency long before it becomes clinically manifest. The results of studying 274 adults by means of a Birch-Hirschfeld visual photometer and data collected from the literature show that mild to moderate degrees of vitamin A deficiency are common among many supposedly healthy adults. Financial reasons, peculiarities in choice of foods, ignorance of a proper diet and a desire to reduce weight were among the factors leading to deficiency. Vitamin A deficiency may occur even if the amount ingested daily is theoretically adequate if any condition is present which (1) increases the metabolic need for vitamin A, (2) interferes with the proper absorption from the gastrointestinal tract or (3) interferes with the conversion of carotene or storage of vitamin A in the liver. Vitamin A deficiency is probably a constant feature of liver disease and does not respond to the usual oral doses of vitamin A.

- Darier's Disease with Malignant Transformation. H. Characht, Brooklyn.—p. 480.

Multiple Glomus Tumors of Order of Telangiectases.—Weidman and Wise's patient exhibited forty-eight lesions of the glomus tumor type. Some of them occurred on sites other than the extremities; i. e., on the cheeks, shoulders and buttocks. There were certain features in the case which might arouse criticism against the diagnosis of glomus tumor, particularly the painlessness and the absence of demonstrable

nerve tissue on histologic examination. The authors believe that in their case telangiectases of glomi (lacking in nervous tissue) could account for the lesions, and they feel that perhaps the same explanation applies to cases reported by other investigators. It is suggested that some so-called glomus "tumors" are of the order of telangiectases, although others must be regarded as hamartomas or even as neoplasms. Clinically, however, the lesions bore not the slightest resemblance to cutaneous telangiectases of any variety.

Unsaturated Fatty Acids in Eczema.—Epstein and Glick further examined the iodine numbers of the blood lipids both in infants and in adults with eczema and compared the change in the iodine number with the condition of the skin in patients receiving oral treatment with oil. Studies of the iodine numbers in cases of cutaneous diseases other than eczema, i. e., psoriasis, acne vulgaris, xanthelasma and xanthoma, are also included. For the most part the disorders of these patients were of a particularly resistant type which had failed to clear after various forms of treatment. In four cases of infantile eczema the iodine numbers of the blood were determined. One of the babies, aged 3 months, received 2 teaspoonfuls of linseed oil by mouth three times daily for three months without any effect on the progress of the condition. One baby, aged 15 months, the iodine number of whose blood was not determined, received 2 teaspoonfuls of linseed oil three times daily for five months without improvement attributable to the therapy. There were seven children and one young adult whose eczema had begun in infancy and who had had recurring attacks since. The patients' ages varied from 11 to 18 years. The adult was 26 years old. Two patients in this group had received no linseed oil, while the others had taken half an ounce (15 cc.) of linseed oil three times a day for one month or longer. Two patients exhibited a flare up on one occasion during the period of treatment with oil. Only one patient with a disorder of a mild type definitely improved, but it was impossible to attribute this improvement to the oil therapy. Of the twenty-three adults who presented the various clinical types of generalized eczema, neurotic eczema, infectious eczematoid dermatitis and seborrheic eczema, eleven took 2 ounces (60 cc.) of linseed oil daily for from one to five months, but in no instance was there a definite beneficial effect on the eczema. In a group consisting of twelve patients with psoriasis, six with acne vulgaris, three with xanthoma tuberosum and one with xanthoma palpebrarum, no definite correlation could be observed between the iodine number of the blood, which varied considerably, and the clinical manifestations of the disease.

Peroral Endoscopy. L. H. Clerf, assisted by D. C. Baker Jr., Philadelphia.—p. 314.

Osteomyelitis of Otitic and Paranasal Sinus Origin.—Behrens reemphasizes the importance of osteomyelitis of the skull, discusses its various aspects, stresses its insidious onset and the disproportion between the external symptoms and its real gravity, asks for earlier recognition and adequate treatment of the rapidly progressive type and gives summaries of his seven cases. In the majority of cases, osteomyelitis of the skull follows surgical intervention and is also more serious from a prognostic standpoint than that which arises spontaneously. One should never operate on the sinuses unless the indications are clear cut, but when necessary one should operate promptly and expose the area adequately for good drainage. Nutrition of the bone will be impaired if pus or necrotic material is confined. The use of any instrument that rubs infected material into rough edges of bone, such as the rasp or the curet, should be avoided. The condition should be classified into the localized, or self-limited, type or the progressive type as soon as possible, so that appropriate treatment

may be instituted early. When radical treatment is necessary, one should use it promptly and thoroughly, in stages if necessary. Transfusions should be given preoperatively, postoperatively and intercurrently; the immunotransfusion is especially recommended. Supportive treatment should not be forgotten, regardless of the active treatment. Regeneration of bone in cranial defects is usually good, though it may take several years.

Typhoid Carriers Among Food Handlers.—Scott discusses the collection of specimens of the intestinal discharges for laboratory examination of some 7,040 persons engaged in handling food in its various forms. Of 2,138 dairy employees who submitted specimens for laboratory examinations 2,070 specimens were found to be negative for *Bacillus typhosus*, while 105 were received in a condition unsatisfactory for bacteriologic examination. Seven persons applying for employment in dairies were found to be excreting typhoid bacilli in the intestinal discharges. When expressed as a percentage, the number of positive typhoid carriers detected in this group amounts to the apparently insignificant figure of 0.32 per cent. However, when it is considered that milk is an exceptionally fine medium for the growth of typhoid organisms, the danger to the milk-consuming population, had these seven carriers been permitted employment in dairies, is vast. Many epidemics have been reported that have been traced to the employment of a single typhoid carrier in a dairy. While the number of typhoid carriers among dairy workers appears small, the detection and exclusion of these carriers from milk handling has been a valuable means of safeguarding the health of the citizens of the county. The menace of the typhoid carrier in cafés, restaurants, hotel dining rooms and other types of eating places is usually considered to be somewhat less than that presented by the carrier working in a dairy. There were 2,327 food handlers who submitted specimens of the intestinal discharges for laboratory study. Of these, 2,188 proved negative on examination, 132 were found to be unsatisfactory for examination and seven were found positive for *Bacillus typhosus*. Some 440 fecal specimens from soda fountain employees were obtained, of which number 424 were negative for *Bacillus typhosus*, while in sixteen cases the specimens were unsatisfactory for laboratory study. These soda fountain employees constituted the only group of the food and beverage handlers that failed to yield positive typhoid specimens. Had the series of specimens been larger, some typhoid carriers would undoubtedly have been detected among this class of workers. The cooperation of 732 employees of bakeries was enlisted for the study, of which 675 submitted specimens which were negative for *Bacillus typhosus*, while in fifty-three cases the specimens were unsuitable for laboratory study. Four persons were detected who had typhoid bacilli in the intestinal discharges. Of 629 specimens from employees of grocery stores and meat markets 578 were negative for *Bacillus typhosus*, while fifty specimens were unsuited to laboratory investigation. One typhoid carrier was detected. In a miscellaneous group

of food handlers 705 of 749 intestinal specimens did not show *Bacillus typhosus*, while in forty-three cases the specimens were unsatisfactory for laboratory examination and study. One typhoid carrier was detected in this group of miscellaneous food handlers. When the figures for the series are reduced to percentages, it is found that 94.9 per cent of the specimens were negative for *Bacillus typhosus*, that 4.8 per cent were unsatisfactory for laboratory examination and that 0.3 per cent were positive for *Bacillus typhosus*.

Observations on Prediabetes.—Rony believes that the high incidence of obesity in diabetes indicates that some relationship exists between these two conditions. In consequence of this contention the presence of low sugar tolerance in obese persons has come to be regarded as a danger sign of diabetes (prediabetes). This prognostic evaluation is the more conspicuous as low sugar tolerance in other clinical conditions is, as a rule, not thought to be conducive to diabetes. He has had twenty obese patients with low sugar tolerance under observation for from one to nine years in order to find out when and under what conditions manifest signs and symptoms of diabetes would appear. None of them developed diabetes. As the patients received instructions to follow a low caloric diet, one might think that the undernutrition was instrumental in preventing the development of diabetes. However, at least six of the patients failed to restrict their food intake. It appears therefore that low sugar tolerance observed in obese persons is not, in itself, indicative of a danger of diabetes. In this respect low sugar tolerance in obesity does not seem to differ from the low sugar tolerance observed in other conditions. However, there is a notable difference between obese persons with low sugar tolerance and normal persons: the former invariably show a marked improvement of their sugar tolerance, while the latter are known to respond with a marked decrease of sugar tolerance. The author suggests that this peculiar difference may be due to the rôle of the fat tissue in blood sugar regulation. During the first three hours following a dextrose test meal, dextrose accumulation in tissues other than the liver constitutes the major mechanism of blood sugar regulation. There is uncontested evidence that among other tissues the fat tissue may prominently participate in the mechanism of blood sugar removal after dextrose ingestion. Previous undernutrition tends to make the fat tissues capable of absorbing large amounts of sugar from hyperglycemic blood. The basic effect of undernutrition on carbohydrate metabolism—be it to decrease insulin sensitiveness or something else—

may be the same in normal as in obese persons. In individuals with small amounts of fat tissue, this effect appears in the form of decreased dextrose tolerance. In persons with large amounts of excess fat tissue the same effect is compensated by accumulation of carbohydrate in the fat tissue, with the result that the blood sugar time curve becomes flatter, giving the picture of improved dextrose tolerance.

Rat-Bite Fever with Demonstration of *Spirillum Minus*.—Bloch and Baldock report their case of rat-bite fever, in a girl 3 years of age, because among more than eighty cases of the disease reported from twenty-three states only thirteen had the diagnoses proved by the demonstration of the causative spirillum and because no authentic case has yet been reported from Kentucky. In searching the darkfield preparations for spirilla, after intraperitoneal inoculation of white mice, it was observed that often for the first hour after the drop of blood was placed on the slide no spirilla could be found; then they would begin to appear, shooting to and fro in the spaces among the red cells. In addition to the spirilla, several other moving bodies were seen, which might possibly cause confusion in diagnosis, if misinterpreted: a motile bacterium appearing in the preparations after an hour or two, a very fine, wavy, scintillant filament attached to red cells and fluttering in currents in the plasma and a small, refractile, rapidly moving particle seen inside the red cells, especially if hemolysis has been produced by adding distilled water to the preparation. Both of the last two objects are seen in normal mouse blood. A fourth possibility of error is the occurrence

of spirilla in the blood of the mouse before inoculation. For this reason a negative examination, preceding the positives, is important as a control.

Late Results of Treated Childhood Hypothyroidism.—Bayer and Snoke give the original status and progress of two children with thyroid deficiency, onset approximately at 1 year and 2 months, respectively. They have been followed under treatment from approximately ages of 4 to 18 years and 2 to 11 years. Both children had at the beginning the appearance and build characteristic of thyroid deficiency and a significant retardation in height and in bony and mental development. There was complete restitution of osseous development in both children. The older girl has developed a nicely proportioned body with quite a delicate face, but she has remained permanently dwarfed and her intellect has not developed beyond the ten year six months level. The younger one, on the other hand, has retained her thickset build but has compensated completely in height and mentality.

Effect of Nicotine-Containing Diets on Estrous Cycle.—Wilson and De Eds noticed that the feeding of diets containing 0.025 per cent of nicotine definitely altered the estrous cycle. The facts that the rats ate less than the normal amount of food and that an equally severe estrual disturbance was produced by decreasing the intake of an adequate diet support the idea that the results were due to a state of malnutrition rather than to a direct action of nicotine. This is in harmony with the existence of normal estrus in rats reported by others, in which the nicotine was injected periodically and presumably did not interfere with a normal food intake. The decreased food intake resulting from oral ingestion of nicotine in the food is due possibly to gastro-intestinal disturbances, one of which is probably an impaired appetite.

Infectious Diarrheas in Children.—In 194 cases of true infectious diarrhea seen during a period of four years, Rose and Schapiro found that in the District of Columbia the greatest number of cases are due to Eberthella paradysenteriae Hiss, while workers in Maryland, West Virginia and New York find that from 25 to 80 per cent of their cases are due to Eberthella paradysenteriae Flexner. The reports found in the literature relating to the bacteriology of the stools from infants with diarrhea show great variation as to those in which the dysentery bacillus was found. The lack of uniformity seemed to depend on (1) the technic used in procuring material for culture, (2) the type of patient under observation, (3) seasonal variation in incidence of dysentery infection and (4) geographic and environmental locality. The fact that there is no characteristic lesion found in the gastro-intestinal tract of the majority of infants succumbing to this condition indicates that factors other than gastro-intestinal damage must be operative, at least in those cases in which such specific disease as dysentery can be excluded. The question of age distribution is of prime importance if one is to seek adequate measures to combat this scourge of infancy. The study of the age distribution and racial distribution of the infectious diarrhea at the Children's Hospital brings out the very important point of the higher incidence in Negro children, mainly because of their socio-economic status and accompanying ignorance. A close inspection readily reveals the prime factors which are the causative or rather catalytic factors in the development of dysentery. The majority of the white patients came from a similar socio-economic status: small hamlets and towns of nearby Virginia and Maryland. The problem apparently hinges largely on the socio-economic status of the patient's parents. The highest incidence occurred between the ages of 6 to 12 months. It is at this period in life that the baby is first weaned and comes in contact with food of a nature not prepared especially for him. It is during this time that most of the noninfectious diarrhea are apt to occur, since it takes some time for the gastro-intestinal tract of the infant to accustom itself to a new type of diet. It is a well known fact that rarely does dysentery develop in exclusively breast-fed infants.

Effect of Barometric Pressure on Incidence of Cerebral Hemorrhage.—To determine whether cerebral hemorrhage is influenced by atmospheric pressure, Kamman studied the necropsy of the last case of cerebral hemorrhage that was acceptable for study (Oct. 4, 1935) and worked back through the records until a series of 150 cases had been obtained (Sept. 19, 1927). The greatest percentage of deaths from cerebral hemorrhage occurred during the seventh decade in men and during the fifth in women. When the direction in which the

barometer was moving is considered, it is found that it was rising in eighty cases, falling in sixty-five and stationary in five. In other words, a change in barometric pressure occurred when 145 of the 150 patients died. In 55.2 per cent it was rising and in 44.8 per cent it was falling. Since a trace of a fall occurs twice as often as a trace of a rise, whereas a great rise occurs eight times as frequently as a great fall, it seems that, even if the data are not sufficient to study the relationship between the incidence of cerebral hemorrhage and barometric pressure by actual statistical methods of correlation, an approach to the problem may be made by studying the frequency distribution of the change in barometric pressure during the twenty-four hour period preceding the day on which the hemorrhage occurred. By computation of this frequency distribution it is observed that the average change in barometric pressure for the twenty-four hour periods preceding days on which cerebral hemorrhage occurred is $+0.074$ inch of mercury. Obviously since the general level of atmospheric pressure is not changing over long periods of time, the theoretical average change for all days in extended time would be zero. The series of 145 cases considered, therefore, indicates that cerebral hemorrhage is associated with periods of increasing barometric pressure. The standard deviation in the table, when calculated mathematically, is 0.2426, giving a standard error of the mean of ± 0.0202 . Since 0.074 is more than three times greater than the standard error, it appears entirely reasonable to expect that the value would be proved statistically significant if the data on barometric change in extended time were available.

Results of Total Thyroidectomy in Heart Disease.—

Because of the encouraging reports concerning patients in whom total thyroidectomy had been carried out for heart disease and after actual interviews with such patients, Claiborne and Hurxthal performed their first total thyroidectomy on a patient with heart disease in the Lahey Clinic in December 1933. Since that time twenty-seven patients have been operated on, the last operation having taken place one year ago. Their results have been fairly satisfactory in some cases. This appears to have been due in large part to the fact that many of the patients selected for operation were not extremely ill. In some cases they might have been symptom free while on a regimen of partial rest and inactivity. The average patient is a great deal more careful in following instructions with regard to rest and work after an operation than before. In following the patients with angina pectoris after a total thyroidectomy, it has been obvious that the amelioration of pain is a more or less temporary affair. The grading of the results has had to be changed on several occasions because of favorable effects at first and less satisfactory results later. This does not necessarily discredit a therapeutic procedure, because the progression of the disease must be considered in tabulating results over a period of years. The decrease in the number of total thyroidectomies performed at present is indicative of a swing back from an enthusiastic trial of a new procedure. Physicians caring for patients at home after the total thyroid-

ectomy are noticing, at times, that these patients are in a condition similar to that present before the operation, and consequently they are not so anxious to have other patients undergo such a procedure. There are some patients in whom the operation of total thyroidectomy seems justifiable; however, they are few.

Immune Reactions in Patients with Gonococcal Infections.—Keefer and Spink declare that the gonococcus is killed in vitro by lysis. This is accomplished by a sensitization of the organisms by antibody, and their destruction is completed by complement. There is no evidence that phagocytosis of organisms is important in this process. Different strains vary in their invasive properties, and this is dependent on the presence of natural bacteriolysins and on the ability of the gonococci to survive in areas abundantly supplied with mucus. During and following a gonococcal infection, the bacteriolysin titer of the blood increases. This is seen more often when there are metastatic lesions, such as arthritis. A study of the bactericidal content of synovial fluid indicates that it may be the same as the blood when the fluid is sterile and that it may be lower when the fluid is infected. The presence of mucin may reduce but does not abolish the action of antibody. This is not caused by an alteration of the complement titer of the plasma or synovial fluid. There is some evidence that it interferes with the sensitization of organisms. The addition of antigenococcus serum to blood in vitro and in vivo increases the bacteriolytic titer of the serum. This is of some practical importance in gonococcal bacteremia without endocarditis.

Meningococemia Without Meningitis.—Goundry and Phalen cite a case of meningococemia unaccompanied by meningitis, which began with chills and fever and was accompanied by headache, joint pain and mental apathy. This was followed by profuse sweating and a generalized rash resembling typhoid roseola. The blood count showed a moderate leukocytosis with a preponderance of polymorphonuclears. Meningococci were found in the blood stream early in the attack. As the patient improved, the blood cultures became negative. There appeared to be no indication for cultures from the petechia and spinal fluid. This condition is probably more common than one realizes because facilities for blood cultures are not always at hand, and enriched culture mediums must be used for the isolation of the meningococcus. The physician is often unmindful of this disease and may easily overlook it, especially in the milder cases. The triad of chills, arthralgia and skin eruption should prompt one to secure an early blood culture. From the therapeutic point of view, specific serum therapy seems the treatment of choice.

Native Agglutinins for Brucella in Blood Serums.—Agglutinins of the Brucella group of organisms have been shown to exist not only in the blood serums from undulant fever patients but in the blood serums of apparently normal individuals as well. Because of this, Hunt and Noll studied the extent and significance of these native agglutinins in 1,000 specimens of blood that were collected without selection of cases from patients or blood donors admitted. Of the 1,000 samples 195 gave positive reactions. Of this number 106, or 10.6 per cent, were considered without significance and eighty-

nine, or 8.9 per cent, significant. Of the 195 positive reactions, 177 reacted both with the Brucella abortus and the Brucella melitensis antigens. Of these 177 reactions, 153 reacted more strongly with Brucella abortus and twenty-four more strongly with Brucella melitensis. Of the remaining positive reactions, fifteen reacted only with the Brucella abortus antigen and three with only the Brucella melitensis antigen. It is concluded that the Brucella abortus agglutinins are far more frequent in human blood serums of individuals of central Pennsylvania than are the agglutinins of the Brucella melitensis, for out of a total of 195 positive reactions 168, or 86.15 per cent, reacted either more strongly or only with the Brucella abortus antigen.

Treatment of Undermining Ulcers with Zinc Peroxide.—Since the publication of their first reports on the favorable effect of zinc peroxide on anaerobic and micro-aerophilic infections, Meloney and Johnson studied in some detail nineteen other cases with chronic undermining burrowing ulcer caused by a micro-aerophilic hemolytic streptococcus. Bacteriologic laboratories equipped to do anaerobic bacteriology are of utmost importance in the recognition of these cases. It would be well if the American College of Surgeons would require class A hospitals to be prepared to do adequate anaerobic bacteriology. The careful application of zinc peroxide will almost invariably halt the spread of this infection. There are certain essential conditions for the success of this treatment. First, the zinc peroxide must have certain physical properties that will provide the necessary environment to inhibit or destroy the causative organisms. These properties may be determined by a simple laboratory test. It must be heated at from 130 to 140 C. for from one to four hours to sterilize it and

mobilize the oxygen. When it is suspended in ten parts by weight of distilled water it sediments rapidly, leaving a clear supernatant fluid. In the course of an hour bubbles of oxygen begin to form in the sediment, which after twenty-four hours becomes flocculent and curdy with the evolution of a considerable quantity of oxygen gas. Five grams in 50 cc. of distilled water should liberate from 10 to 20 cc. of oxygen in twenty-four hours. The next requirement for the successful use of zinc peroxide is that every part of the infected surface must come in contact with it. If this is not possible without operation, undermined flaps and sinuses should be widely opened and all the infected surfaces should be flooded with a creamy suspension of the powder in distilled water, approximately equal parts of water and powder being used. This should be put on in the form of a thick cream which is able to run to all parts of the wound. The wound should then be packed with fine-meshed gauze or silk ribbon soaked in the same material and sealed with petrolatum or zinc oxide gauze to prevent evaporation, drying, crumbling or caking. A fresh dressing should be applied every twenty-four hours. As soon as the undermined flaps have sealed down and new skin has begun to grow in from the margins, the ulcer may be covered with skin grafts of the Reverdin type held in place with a single layer of coarse meshed gauze, sealed to the skin margins with collodion; then a dressing of fine meshed gauze soaked in saline solution should be applied and sealed over with petrolatum gauze to prevent evaporation. The compresses should be removed in twenty-four hours and a thin suspension of zinc peroxide applied over the coarse meshed gauze and sealed in turn with an impermeable covering. Forty-eight hours after the skin graft, the coarse meshed gauze may be carefully removed, leaving the grafts well supplied with blood. Thereafter the grafted area may be flooded daily in the same way as the rest of the wound with a creamy suspension of zinc peroxide. If possible, frequent cultures should be taken of various parts of the wound to indicate the presence or absence of the infecting organism. This disease should not be confused with the gangrenous type of chronic ulceration.

Effect of Hyperthyroidism on Diabetes Mellitus.—Smith points out that there is a distinct similarity between these two diseases in their effect on the human body. Some of the symptoms and signs that are almost interchangeable in hyperthyroidism and diabetes mellitus are: (1) rapid loss of weight, (2) nervous irritability which is more marked in the hyperthyroid state, (3) low respiratory quotient, (4) increased protein metabolism and (5) absent or diminished liver glycogen. In the combination of the two diseases, one is dealing with a patient who may have a metabolic rate twice normal and a caloric intake which may satisfy only one half of his total needs. It follows, therefore, that the remainder of the caloric requirement must come from the patient's own body fat. With the entrance of such a large amount of fat into the metabolic mixture plus the inability to oxidize a normal amount of dex-

trose, the tendency to acidosis is greatly increased. The problem resolves itself into adequate dosages of insulin to cause burning of the proper amount of dextrose and a lowering of the metabolic rate by the use of iodine. The further control of the hyperthyroid state may be accomplished with either surgery or roentgen therapy. The results of irradiation and surgery of the thyroid are equally successful in the control of primary hyperthyroidism. In the condition of adenoma of the thyroid with secondary hyperthyroidism, surgery is the therapeutic method of choice. The rôle of the thyroid in its actions on carbohydrate metabolism is not definitely known; however, it has been shown that it helps mobilize the liver glycogen and, in the hyperactive state, renders a patient insensitive to insulin. This may all be explained by its governing influence on the metabolic rate. For instance, conditions which lower the metabolic rate, such as fasting or wasting diseases, apparently help an uncomplicated diabetes, and conditions which increase the metabolic rate, such as fever, injections of epinephrine, pregnancy or a diet high in protein, intensify a diabetic state.

Masculinizing Tumors of Ovary.—Maxwell points out that virilism in women may develop from a variety of causes, as is exemplified by the heterosexual manifestations associated with pituitary basophilic adenoma, adrenocortical tumors and hyperplasia, pseudohermaphroditism, the so-called Achar-Thier's syndrome and ovarian neoplasms which possess characteristic biologic function, such as arrhenoblastoma and adrenocortical ovarian inclusions. While it is accepted that sex of the individual is determined at the time of fertilization, the occurrence of heterosexual phenomena leads to speculation as to the completeness of the demarcation of the characteristics regarded as specific to either sex. The embryonic bisexual anlagen of the gonads offer a medium for sexual ambiguity. Nor is there mutual exclusion even in normal individuals of the gonadal secretions of the opposite sex, for androgen has been demonstrated in the body fluids of women and estrogen in the tissues of men. These observations lead to the conclusion that, while the sex of the individual is determined at the moment of the union of the maternal and paternal cells, the somatic expression and biologic function of the sexual apparatus are largely dependent on the nicety of balance and the orderly interrelationship of all the complex units of the endocrine system.

Chronic Miliary Tuberculosis in Children.—Fish presents a survey of the literature, discusses the differential diagnosis and cites ten cases of chronic miliary tuberculosis occurring in childhood with recovery in four. Microscopic sections of the lungs in three of the fatalities demonstrated the healing process in individual miliary nodules. From his observations he concludes that miliary tuberculosis runs a chronic course more frequently than is generally recognized; recovery occurs in a fair proportion of these chronic cases. Recovery is most common when the nodules are confined to the lungs, but it may also take place in generalized cases and even when the onset of the illness is moderately acute. The pathology of the lesions in chronic and acute cases is essentially the same. Healing of individual miliary tubercles takes place by a process of fibrosis which usually leads to their complete disappearance from the pulmonary roentgenograms. Massive caseous glands in the upper mediastinum are observed frequently in the juvenile type of chronic miliary tuberculosis; the presence of these glands may be responsible for the tendency to recurrent episodes of tuberculous bacillema, which is a feature of these cases. Any one of these episodes may give rise to fatal meningitis; the risk of this complication occurring is, however, considerably diminished if strict rest in bed is maintained until the roentgenogram is clear.

Plasma Phosphatase in Diagnosis and Prognosis of Rickets.—Morris and his associates try to assess the value of plasma phosphatase as a diagnostic test for rickets and also as a means of determining the presence and rate of healing. The results are based on the examination of 506 children less than 2 years of age who either had manifest rickets or might possibly have been suffering from the effects of vitamin D insufficiency. The method employed for estimating phosphatase was that devised by Jenner and Kay. In a series of healthy infants of the same age the limits for plasma phosphatase fell between 3.4 and 10.5 units, with an average of 6.92 units. Any value above 11 units has been considered to be higher than normal. In 84.1 per cent of the 506 children with clinical or roentgen evidence of rickets the plasma phosphatase was increased above normal limits. It is suggested that a rise in plasma phosphatase is an earlier manifestation of the rachitic state than that provided by ordinary clinical or roentgen examination. A rough parallelism was observed between the height of the phosphatase and the severity of the rachitic process, but the level of the phosphatase cannot be taken as an index of severity in the individual patient. A moderate degree of correlation was observed between the rise in phosphatase and the fall in phosphorus and calcium phosphorus product, especially the latter, and it would appear that, of the three, an increase in plasma phosphatase is the most delicate test of the rachitic state, although an alteration in phosphatase alone should not be used as conclusive evidence of the presence or absence of rickets. The plasma phosphatase continues to rise in untreated active rickets. Administration of vitamin D prevents this rise and causes a fall in from two to three weeks. The rate of fall depends on the dosage of vitamin D. On the administration of ordinary therapeutic doses, normal limits may not be reached before the lapse of more than three months. The phosphatase is increased whenever the supply of calcium is unable to meet the demand of the bone cells as a result of defective intake of minerals or vitamin D.

Nasopharyngeal Sepsis in Cases of Mental Disorder.—Graves summarizes the observations and treatment of 2,056 cases of mental disorder—mainly certified—by three ear, nose and throat surgeons working separately during the nine years from 1927 to 1935 in the Birmingham Mental Hospital. On admission all patients had a routine investigation of the mental and physical states, including a preliminary examination for disease conditions in the ear, nose and throat. Patients in whom a history of mental or physical symptoms suggested such a condition were further investigated by the visiting rhinologist, employing special methods of examination when desirable. On these observations and after consultation between the visiting and resident medical staffs, cases thought suitable on mental and physical grounds for further investigation and likely to tolerate the appropriate anesthesia were selected. Appropriate treatment was then given, although this stage of active investigation and treatment was not generally carried out until the mouth was free from sepsis. In tuberculosis, hemoptysis may first draw attention to the disease. Symptoms of dementia paralytica may be the first indication of syphilis. Mental depression following influenza may continue until an area of residual infection in the nasal sinuses is treated effectively, when the psychotic disturbance passes away. In some cases of nasal sinus disease mental symptoms may be among the first of the signs and symptoms directing the attention of the family or physician to the fact that the patient is ill. In some cases in which nasal sinus disease is present an examination of the nasal passages may show only doubtful signs or none at all, the condition being one of closed sepsis. In such cases an inflamed sinus is unable to discharge its exudate owing to closure of its ostium, and as a result internal absorption and extension of inflammation takes place from the diseased membrane. If drainage is prevented, complications arise, one of which is delirium, which sometimes precedes death. Should the patient survive, mental disorder and perhaps certifiable insanity may ensue and continue, as the result of the persistence in an important site of a small area of "occult" sepsis, which acts as the primary port of entrance of infection and is responsible for the obvious and dramatic collection of pus elsewhere.

Achlorhydria an Etiologic Factor in Pruritus Vulvae.

—Swift points out that a common factor is present in pruritus vulvae, leukoplakia, kraurosis vulvae and leukoplakic vulvitis and that this factor is achlorhydria, which causes a deficiency of absorption of vitamin A from the diet. Changes in epithelial structures result from this deficiency. These skin changes do not always conform to the same clinical type but depend on the stage of the disease, and so in the past they have been given many different names. However, the original cause is the same in all types. Occasionally an achlorhydria is not present, and it has been found that in these cases the diet itself is deficient in vitamin A. The addition of diluted hydrochloric acid to the normal diet of forty-two women suffering from intractable pruritus vulvae with achlorhydria relieved the pruritus in the majority of cases with great improvement of the local vulval condition. Vitamin A in the form of cod liver oil should also be given. Excision of the vulva is not necessary in these cases except in those in which a malignant change is suspected. Epithelioma of the vulva should become increasingly more rare if this chronic irritation is relieved at an early stage by the giving of oil and acid. Achlorhydria is often present in cases of pruritus vulvae in which the irritation has not been relieved by curing the supposed primary cause. The diluted hydrochloric acid is given by mouth, a teaspoonful in a glass of water. Half of this solution is to be sipped during the meal and the other half drunk after the meal. The acid is to be taken with each meal. The acid must be taken for many weeks, as in a number of cases the irritation has returned when the patients have left off the acid, if only for a few days. A teaspoonful of cod liver oil is taken three times a day. Local treatment is prescribed to patients with very bad irritation. A cream made of zinc oxide and starch with sweet oil of almonds has been found to be most soothing. It can be cleaned off the vulva by wiping with more almond oil. In other cases a local anesthetic ointment has been used. However, as soon as the patient had started taking the hydrochloric acid the pruritus usually started to improve. Any associated cause or causes should also be treated. When infection has been superimposed on the hypertrophic or atrophic conditions, local treatment should be given, such as sitz baths and the application of a soothing lotion. At the same time the original cause, the achlorhydria, should also be treated with acid.

Variations in Number of Blood Platelets in Women.—Genell performed 1,433 determinations on thirty-eight women in studying the variations in the number of blood platelets during the normal menstrual cycle. On the first day of menstruation there is a fall in the number of platelets from about 230,000 per cubic millimeter to about 200,000. During the first ten days of the cycle there is a slow rise in the number of platelets, the culmination being reached about the eleventh day with about 265,000 per cubic millimeter. From the eleventh to about the twenty-first day the number slowly declines to about 230,000. During the last week of the cycle the number remains constant at 230,000 until the sudden diminution occurs at the onset of menstruation. These variations are not due to variations in the concentration of the follicular hormone. The author shows that a similar increase in platelets occurs after parturition, after abortion and after operation. As the change in the concentration of estrogen after parturition and abortion is quite the reverse of that after menstruation, and the estrogen can have no connection with postoperative changes, it is not possible to regard the postmenstrual increase in platelets as standing in a causal relation to the hormone of the follicle. The author explains the analogous increase in platelets after menstruation, parturition, abortion and operation as a reaction of the organism to resorption of necrosed material and he finds this explanation corroborated by the fact that the degree and duration of the platelet increase on these different occasions occur together with the degree and duration of the resorption.

Nervous Anorexia and Physical Constitution.—Sheldon emphasizes physical aspects of nervous anorexia which suggest that in some cases there is an underlying hypofunction of the anterior pituitary, but he does not intend to amend the current conception of the disease—that the loss of appetite begins in response to some psychologic need and, once established, is perpetuated as a hysterical condition. This conception is borne out by the fact that physical treatment for the anorexia is out of place, the patients being able to recover their appetite with suitable psychologic help alone. A common emotional cause will explain both the anorexia and the amenorrhea often associated with it. But in the chain of events that leads to the amenorrhea the pituitary must be involved, and there is often evidence that the functions of this gland are already subnormal. The deficiency may show itself by small height, delayed onset of puberty, infantile uterus, adolescent obesity and in other ways. The symptoms of nervous anorexia—loss of appetite and weight, amenorrhea, low basal metabolism and alterations in carbohydrate metabolism—are so similar to those of Simmonds' disease as to suggest that in these cases one is really dealing with a "functional" Simmonds' disease—a pituitary "black-out" of psychologic origin. It is possible that only a certain type of body-mind reacts in this particular way, that the infantility which often characterizes the psychologic background may be the counterpart of an actual endocrine infantility.

Fate of Colloidal Thorium Dioxide in Cerebral Arteriography.—Northfield and Russell describe four cases in which, after arteriography with colloidal thorium dioxide, histologic evidence was obtained of retention in the lumen or walls of

the cerebral vessels or in the perivascular macrophages. Such retention appears to be liable to take place in the neighborhood of compressing lesions, such as meningioma, a large hemorrhage or chronic abscess. The aggravation of clinical symptoms that was observed in two of the cases and the retardation of recovery from operation in one may be attributable to this occlusion of vessels by colloidal thorium dioxide. The use of colloidal thorium dioxide is inadvisable unless exact diagnosis is unattainable without it.

New Complete Range of Splints and Fracture Reducing Apparatus Designed on "Universal" Principle. L. Buchanan.—p. 227.

Influence of Temperature on Blood Sedimentation Rate.—Rosenthal declares that a sedimentation index of say 17 mm., measured on a summer's day, may well be the equivalent of 5 mm. in the same subject on a winter morning; while a "diagonal curve" on a hot day might have the same significance as a "horizontal line" during a cold spell. A standard temperature for the performance of the test is eminently desirable: 68 F. is suggested as a convenient standard. When it is impracticable to perform the test under standard conditions, the practice of noting the room temperature when the readings are quoted should be followed so that due provision for temperature variation may be made. Mathematical correction for temperature variation at present is not practicable. The disparity between the sedimentation index and the cell volume indicates approximately to what extent the former is a measure of the sedimentation velocity, and the recording of the cell volume at the end of each test would be a valuable procedure. By centrifugating the tube, or immersing it in a water bath at about 100 F., the figure for cell volume could be rapidly, if approximately, obtained. The height of the column of cells, that is, of the sediment, quoted as a percentage of the total height of the blood column (which, in Cutler's method, is approximately 5 cm.) is a suitable index for cell volume. A complete statement on the result of a blood sedimentation test would then read somewhat thus: (1) for "slow" blood: 8 mm., 63 F., 55 per cent; (2) for "fast" blood: 28 mm., forty minutes, 63 F., 40 per cent.

*Central Renal Abscess with Hematuria. A. Leruitte.—p. 689.
Congenital Stricture of Aortic Isthmus. C. Lian and J. Facquet.—p. 708.

Bazin's Indurated Erythema and Pregnancy. J. Piérard.—p. 712.

Central Renal Abscess.—Leruitte draws attention to a clinical variety of pseudoplastic renal abscess that has not yet been described in urologic literature. It manifests itself by profuse hematurias but by no other clinical signs that would lead one to suspect suppuration of the kidneys. The etiologic factor is the colon bacillus found alone in the urine. Preceding trauma or previous infections seem to be of little plausibility as to etiology. Pathologically, the kidney in which an abscess develops retains its normal macroscopic aspect for a long time. It becomes tumor-like only when the abscess has penetrated to the periphery. It always opens into the pelvis. The abscess is of the miliary type and, situated mainly in the interstitial tissue, it sometimes also includes glomeruli which are either congested or atrophied, and excretory tubules, some of which are dilated and others show cellular obstruction of the lumen. A conglomeration of miliary abscesses is easier to explain than would be a causative infarct, which would produce deeper and wider destructions. The phenomena of congestion are alone capable of causing hematuria, as it is well known that even the slightest ulceration of a malpighian pyramid will make a kidney bleed, owing to a particular vulnerability of the renal vessels. The clinical examination reveals a temperature of about 98.5 to 99 F. and, on palpation, a localized pain in the costolumbar angle. But the main clinical symptom is continuous painless hematuria supplemented by pyelographic observations of functional deficiency and alterations of the renal pelvis. In the three cases under the author's observation there were vermiform clots presenting veritable casts of the ureter, pus and numerous colon bacilli. One pyelogram showed a lesion in the superior extremity of the left calix whose shadow was less dense than that of the pelvis. Another showed the shadow of the inferior calix together with the lacunary shadow separated from the pelvis owing to compression by the abscess. Differential diagnosis must be made from scurvy, leukemia, purpura, hemophilia and medicamentous hematurias in infectious diseases. Renal tuberculosis, hematuric pyelonephritis and infected renal calculi are all attended by cystic phenomena not existing in pseudoplastic central abscesses of the kidney. The best method of treatment is exploratory nephrotomy, which must afford the assurance that all abscesses have been opened. But Marion maintains that there is no reason for haste unless the symptoms are severe, in which case decortication is not sufficient and nephrectomy should be resorted to. Spontaneous cure is possible in mild cases.

*Pseudofracture of Acetabulum in Children and Ischium Varum. L. Lamy and J. Vincent.—p. 29.
Acute Osteomyelitis Continuing Despite Three Successive Operations Cured by Phagothérapie. A. Raiga.—p. 42.

Pseudofractures of Acetabulum in Children.—Lamy and Vincent examined a number of children referred to them with alleged fractures of the acetabulum. This diagnosis is often made from roentgenograms falsely interpreted. They are dealing with patients whose cartilages have not yet become ossified and in whom the roentgenograms were taken obliquely with the patient in an anteroposterior and somewhat rotated position. The authors could verify this fact by changing the position of the child on the x-ray table. The new roentgenograms thus obtained no longer show any "lesion." By turning the patient on the other side they could obtain the same picture on the unsuspected side. The three primary centers of ossification of the coxa appear between the second and fourth intra-uterine months. At birth they are separated by three cartilaginous lamellae. But the converging center does not correspond to the geometric center of the acetabulum even in the older child. For this reason the inferior cartilage, which is vertical, is not seen in an anteroposterior roentgenogram. If the ilium is in a normal position with no lateral rotation and no anterior or posterior inflexion, the ilio-ischiatic and the iliopubic shadows

appear superimposed. If the ilium is kept vertical but in left to right rotation of about 30 degrees, the posterior part of the cartilage appears below the ilium. If the ilium is somewhat tilted backward but without lateral rotation, the ischium is vertical and appears shortened. If the latter shortening becomes more accentuated, it assumes an ischiopubic direction downward and inward. It thus shows clearly the upper border of the ischium by degaging on the inside the ilio-ischiatic cartilage. Only recently the authors noticed a similar erroneous report in an American journal in which the roentgenogram showed the ischium of the right side displaced downward. The American author even believes that he has corrected the "displacement" by reducing the flexion and abducting the thigh. But the fact remains that the roentgenogram taken several months later shows nothing but a more correct position of the patient on the plate. In the meantime the child also grew and the acetabulum became more ossified. The authors conclude that they are never satisfied with small films. Many roentgenograms may often be necessary and a few modifications of the pelvic posture in order to avoid believing in a fracture with impaction or in a dislocation of the ischial epiphysis. There will also be no reason to speak of ischium varum when there is merely an improper posture assumed by the patient.

 *Dry Trapeziometacarpal Osteo-Arthritis: Rhizarthrosis of the Thumb. J. Forestier.—p. 315.
 Endoscopy and Pleurolysis: Advice to Beginners. P. Weiller.—p. 317.

Dry Trapeziometacarpal Osteo-Arthritis.—After studying about 4,000 cases of rheumatism of the hands, Forestier noticed a degenerative form of arthritis which occurred frequently in the carpometacarpal joint of the thumb. Its symptoms of pain and functional impairment are due to an arthritis in which both bones are involved. Among fifty-seven patients there were fourteen men and forty-three women. The preponderance of women above the age of 50 may have its cause in changes due to the menopause. The onset is marked by pain, which may be spontaneous along the radial aspect of the thumb or caused by vigorous movements or grasping efforts. In rare cases it eventuates in rigidity and functional impotence of the thumb. On examination the metacarpal of the thumb was frequently found fixed parallel with the second metacarpal, from which position abduction was difficult. Often the thenar eminence was so atrophied that the deformed and enlarged first carpometacarpal articulation was visibly protruding. The first stage of the arthritis is characterized by a moderate hypertrophy and slight friction sounds on passive motion. The second stage shows pronounced bony hypertrophy, often attended by swelling and limited abduction. The third stage is marked by considerable bony hypertrophy and eburnation and almost complete ankylosis, as well as external and forward subluxation of the proximal end of the first metacarpal. In the majority of cases the disability becomes bilateral within three years. Physiologically, the hypertrophic changes of the proximal end of the metacarpal and the widening of the trapezium may be due to the presence of osteophytes and to thickenings around the epiphysis, while the capsule remains normal and the synovial membrane shows only slight fibrinous changes. Roentgenologically the articular interspace diminishes until it entirely disappears. The bony texture appears granular and the reticular outlines are quite modified by calcified deposits. The diagnosis is arrived at through routine examination of the hand, and the disorder must be differentiated from tendovaginitis and from traumatic injuries. This osteo-arthritis may begin slowly and be latent for some years, but it has generally a favorable prognosis, except for the esthetic aspect. The treatment is the same as in other arthroses: iodine, sulfur or glandular therapy. Important is the immobilization of the joint and its protection against cold. Various forms of physical therapy were tried with good results. In one painful case the author performed a drilling operation through the trapezium and the base of the metacarpal after a small incision at the base of the thumb. The holes are about 2 mm. wide, made into the bones at right angles without injury to the capsule. The postoperative results are favorable.

- *Abdominal Syndromes in Pleurisy. P. Guglielmetti.—p. 1.
 *Francke's Striae in Pulmonary Tuberculosis. P. Alimenti.—p. 14.

Abdominal Syndromes in Pleurisy.—Guglielmetti says that the development of abdominal and gastric symptoms in pleurisy is a frequent occurrence, especially in patients having a pneumothorax. The clinical symptoms depend on the location and phase, acute or attenuated, of pleurisy. Acute right pleurisy is complicated by an acute abdominal syndrome with the symptoms of acute conditions of the abdomen or of acute appendicitis. There are intense abdominal pain, diffuse or located at the appendicular region, and muscular rigidity. The abdominal symptoms are not related to the amount of pleural fluid. The former may appear in the absence of the latter. Simultaneously with the abdominal symptoms, gastric disturbances develop. Once pleurisy and its consequent symptoms are established, the abdominal symptoms do not improve by removal of pleural fluid but follow a favorable evolution on regression of the general toxic phenomena. Disturbances of the liver and of the gastric motility are rare. In the nonacute periods of right pleurisy as well as in acute left pleurisy the gastric symptoms predominate over the abdominal ones. They consist in anorexia, nausea, a sensation of fullness after meals, digestive disorders and vomiting. Their intensity and evolution depend on the amount of pleural fluid and improve after removal of the fluid. Abdominal pain in left pleurisy is moderate. It is located at the left hypochondrium. According to the author the most important causal factors of the abdominal and gastric symptoms complicating pleurisy are a propagation of the inflammation from the pleura to the phrenic and the thoracic sympathetic nerves and a rupture of the relations of the organs at the abdominal cavity and at the thorax, due to mechanical disorders of the diaphragm. It is possible that the nervous and diaphragmatic conditions created by pneumothorax make the occurrence of causal factors more frequent in the course of pleurisy in patients having a pneumothorax than in normal persons. In the group of thirty-seven cases reported by the author, the abdominal and gastric symptoms were a complication of right, left or bilateral pleurisy in patients having a pneumothorax.

Francke's Striae in Pulmonary Tuberculosis.—Alimenti calls attention to the frequency, significance and importance of Francke's striae in pulmonary tuberculosis. Francke's striae are small cutaneous venous ectasias of red wine color which generally appear near the seventh cervical vertebra. They may be unilateral or bilateral and sometimes form a small Medusa head. The intensity of the color depends on the duration of tuberculosis. According to the author, Francke's striae are a viscerocutaneous reflex which originates in a chronic stimulation from the apex of the lung to the skin. Because of their frequency in pulmonary tuberculosis (45 per cent) they are of diagnostic value, especially in the forms which evolve with few symptoms or no symptoms at all. Francke's striae are also of prognostic value. Their presence shows the existence of fibrocaceous tuberculosis of long duration at the apex, a tendency of the disease to evolve with frequent recurrences, rather than going through a process of stabilization of the disease, and the presence of pleural adhesions.

- Relation Between Reticulocytosis and Regeneration of Erythrocytes. L. Crosetti and G. Bajardi.—p. 273.
 *Hemoglobinuria from Malaria: Treatment with Cevitamic Acid. G. Castrovilli.—p. 279.

Cevitamic Acid in Treatment of Malarial Hemoglobinuria.—Castrovilli reports satisfactory results from the daily administration of a hypodermic injection of 0.1 Gm. of cevitamic acid in a case of nephrohemolytic hemoglobinuria in benign tertian malaria, without jaundice and hemoglobinemia. The injection was repeated a second time. During administration of the treatment and for some time after it was discontinued, the patient was given liberal amounts of lemon juice. Hemoglobinuria completely and permanently disappeared after the first vitamin injection. The platelets rose from 150,000 to 200,000. Malaria was controlled by atabrine and plasmochin.

According to the author, the administration of cevitic acid prepares the body for a general favorable reaction to antimalarial treatment. In the case reported the administration of 0.6 Gm. of quinine and the exposure of the patient's legs to a cold ambient (Ehrlich's test) did not produce hemoglobinuria after recovery of the patient by treatment with cevitic acid took place.

Myocarditis of Productive Type of Probable Syphilitic Origin: Case. T. Castellano, Dacia Deza Cenget and R. Lascano.—p. 367.

Ventricular Contraction in Bundle Branch Block.—Battro and his collaborators state that by obtaining simultaneous graphic records of the venous pulse and the heart apex impulse and of the central arterial pulse and the heart sounds, one is able to ascertain whether the ventricles contract simultaneously or asynchronously. The authors used the procedure in twenty cases in which the electrocardiograms showed right bundle branch block. The electrocardiograms were of the classic type (Lewis, Mahaim and Rothberger) in seventeen cases and of Wilson and his collaborators' type in three. In fifteen cases of the classic group the graphic records showed asynchronism with premature contraction of the right ventricle over that of the left, which was an indication of left bundle branch block. In two cases in the group the contraction of the ventricles was synchronous. In one case in the group of patients having electrocardiograms of Wilson's type, the contraction of the left ventricle took place before that of the right and in two cases in the same group there was no asynchronism. The authors conclude that the electrocardiogram alone is too unreliable to determine the presence of ventricular asynchronism for the diagnosis of complete bundle branch block. By graphically recording the mechanical phenomena of the heart action, the presence and intensity of ventricular asynchronism as well as the location of the lesion on either branch can be ascertained and a reliable diagnosis made.

Water-Sodium Chloride-Nitrogen-Tolerance Test For Detection of Disturbances in Renal Elimination in Obese and Emaciated Persons.

Hildegard Bretschneider.—p. 49.

Water-Sodium Chloride-Urea Tolerance Test.—Weitzmann says that the combination tolerance test with water, sodium chloride and urea, the technic of which he described in an earlier report, is helpful in all cases in which the elimina-

tion of water, salt and urea is impaired. In this paper he discusses different groups of such disturbances. He shows that the acute nephritides, in which permanent anatomic changes are still absent, must be differentiated from the so-called residual conditions, from the chronic nephritides and from contracted kidney. In acute nephritis the combination tolerance test does not permit definite conclusions with regard to the type and severity of the disorder or the therapeutic-dietetic measures. The residual conditions, that is, those in which a cure with defect must be assumed, nearly all show an abnormal behavior in the tolerance test; nevertheless, the elimination of water, sodium chloride and urea is usually adequate. In the chronic nephritides, however, there is usually a retention of water, sodium chloride or nitrogen, or of several of these substances. The combination tolerance test discloses not only the type of the functional disturbance but also the incapacity to compensate for it. The impairment of the elimination involves particularly the sodium chloride, for, if from 12 to 14 Gm. is taken in, less than 6 Gm. is eliminated. The nitrogen elimination is likewise impaired: if from 12 to 15 Gm. is taken in, the elimination is rarely below 8 Gm. The water elimination varies greatly in different cases of chronic nephritis. In contracted kidney likewise the water elimination varies considerably. In severe cases with chronic uremia, polyuria may exist. However, if a cardiovascular insufficiency develops, the diuresis usually decreases. In this terminal stage of contracted kidney the specific gravity of the urine remains constantly the same. After describing and discussing typical cases, the author reaches the conclusion that the combined water-sodium chloride-urea tolerance test is a valuable functional test during all the stages of hemorrhagic nephritis. In comparison to the plain water tolerance test, the combination tolerance test gives more information about the complicated processes of renal elimination, their regulatory mechanisms and their compensatory capacities. The evaluation of the results of the tolerance test permits a more exact dietetic treatment.

Treatment of Visceral Ptosis by Abdominal Support.—Kaufmann points out that Glénard first applied the term visceral ptosis and suggested abdominal supports for its correction. These bandages, which have pads on the inside, lift up the prolapsed organ. The author thinks that they have not been used as much as they should. He gives his attention chiefly to ptosis of the stomach, pointing out that, in view of the hydrostatic pressure balance in the abdominal cavity, it is sufficient to lift the prolapsed stomach, as the other abdominal organs are lifted with it. In case of an obese but dilated abdomen, the prolapsed stomach and the entire abdominal contents can be lifted and drawn backward toward the vertebral column by a specially designed abdominal support. If visceral ptosis exists in thin persons, the support must have a special pad on the inside. After discussing and illustrating the design of the abdominal supports, the author cites histories of patients in whom he found the abdominal support helpful, such as cases of gastric dilatation in pyloric stenosis, a case of severe kyphoscoliosis, a case of gastric dilatation after duodenal ulcer, and a case of ptosis of the stomach after gastro-enterostomy.

Comparative Determination of Cevitic Acid Content of Various Animal Organs. A. A. Policard and M. Ferrand.—p. 308.

Clinical Aspects of Diphtheria.—Otto and Mittag report their observations in seventy-three cases of diphtheria. They found that all three types (mitis, intermedius and gravis) may appear in the course of one epidemic. Healthy bacillus carriers may harbor not only the mitis type but also the intermedius

and the gravis types. In two cases the authors observed first an intermedius type and then a mitis type. In siblings they observed the same as well as different types of diphtheria bacilli. Complications may develop in the presence of type mitis, intermedius and gravis. It was observed that some of the severest complications developed in patients with the mitis type of diphtheria bacillus. The percentage of complications was also highest among the patients with the mitis form. The mitis type predominated in the material analyzed by these authors, but they say that other types have been found to predominate in other regions. However, since it cannot be said that the gravis type of diphtheria bacillus causes severe forms of diphtheria and the mitis type mild forms, the authors suggest that the types gravis, mitis and intermedius be designated as types I, II and III, respectively, so as to avoid erroneous ideas regarding the clinical manifestations of the diphtheria caused by the various types of bacillus.

Encephalography in Differential Diagnosis of Epilepsy.

—Laubenthal shows that encephalography has acquired considerable importance in the differentiation between the hereditary and symptomatic forms of epilepsy. His observations in several hundred cases proved that, with the exception of temporary discomfort and disturbances, encephalography has no undesirable effects. In the cases described in this report he applied the diagnosis of hereditary epilepsy only to those cases in which epilepsy was present among the blood relations and in which there was no record of an exogenic lesion. In summarizing his encephalographic observations in the cases of hereditary epilepsy, he says that a large number show encephalographic changes. There are unilateral or bilateral enlargement of the ventricles, dilatation, particularly of the third ventricle, and occasionally also a lack of ventricular filling on one or both sides. The subarachnoidal filling may be increased, irregular or spotted. However, the author failed to observe in cases of hereditary epilepsy extremely severe (hydrocephalic) degrees of ventricular dilatation, also extensions, displacements and sinusities of the ventricles. He thinks that circumscribed changes in the subarachnoidal filling are rather indicative of a local process, particularly in doubtful cases. He emphasizes that encephalography should always be combined with exact anamnestic studies and careful neurologic examinations, for, although the encephalogram may be the deciding or corroborating factor in the differential diagnosis, it may also fail to clarify it.

Wheal Resorption Time During Volhard's Water Test.

—Medvei and Lehdorff point out that the intake of large amounts of fluid, such as in the Volhard water test, causes a change in the fluid exchange between blood and tissue and vice versa. Immediately after the water has been taken there is a retardation of the passage into the blood of subcutaneously injected uranin; but one hour later the resorption time is

again as before the administration and two or three hours later it is frequently somewhat accelerated. In pathologic processes such as nephritis, carcinoma and icterus, these conditions are different and thus conclusions can be drawn about the condition of the "prekidney." The authors decided to determine whether the more simple wheal test (McClure and Aldrich) together with the water test might not be helpful in the functional examination of kidney and "prekidney." They made the wheal test in connection with the water test in a number of patients and in control cases. They found that there were no significant differences between the resorption time of the wheal (made according to the method of McClure and Aldrich with solution of sodium chloride) before and after the intake of 1,500 cc. of fluid. Thus it is impossible to substitute this simpler test for the more complicated uranin resorption and Volhard test. The authors point out further that their results contradict also Pugliese's observation that the wheal resorption time is prolonged during the water tolerance test and shortened during thirst.

Body Rotation in Disease of Frontal Brain.—Gerstmann shows that spontaneous rotation movements occur not only in disorders of the cerebellum and of the middle peduncles of the cerebellum but also in persons with lesions of the frontal brain. He observed that the latter patients exhibit the spontaneous rotation only when in the erect position. The movements are not so much rotations around the patient's own axis but rather tend to form circles of various radii. The rotation movements appear especially when the patient stands with the feet close together and they become intensified when the eyes are closed. It is also noteworthy that they are not accompanied by vertigo or by changes in the position of the eyes. Passive or active turning of the head influences the symptom in that movement of the head toward the side of the affected frontal brain resulting in an intensification of the rotations in this direction, whereas movement of the head toward the opposite side either has no effect on the rotation or intensifies it in the direction homolateral to the lesion. The author observed further that the symptom of rotation in lesions of the frontal brain is accompanied by disturbances in the equilibrium; that is, by a tendency to fall. However, it appears that the falling movements and the rotations tend in opposite directions. Whereas the direction of the fall is backward or contralateral to the lesion, the rotation is in the homolateral direction. To be sure, this difference in directions is noticeable only as long as the brain lesion is limited to one side. As soon as the other side becomes involved (growth of tumor) this symptom becomes irregular and confused. After pointing out that the combination of rotation and disturbed equilibrium has been corroborated in animal experiments, the author concludes that the rotation movements, although elicitable by lesions in various parts of the central nervous system, nevertheless have aspects that are characteristic for frontal lesions. In case of lesions of the frontal brain, the rotation movements appear only if the patient is in the erect position, whereas in case of cerebellar lesions they are present also when the patient is sitting or lying down.

Neurologic Complications of Pernicious Anemia.—Hitzzenberger says that, if a funicular myelitis exists in pernicious anemia, the most potent preparations should be used. Whereas in pernicious anemia that is not complicated by funicular myelitis an erythrocyte count of about 4,000,000 and a hemoglobin content of 80 per cent may be regarded as adequate, in patients

with funicular myelitis this is not sufficient. In the latter patients, efforts should be made to bring the erythrocyte count up to 5,000,000 and the hemoglobin content to 90 or 95 per cent and even after that the injections should be continued. Depending on the severity of the case, 2 cc. of a potent preparation should be injected daily or every second day, for a period of from four to five months. Thus it is possible to influence even the apparently hopeless cases. There is no danger of a polycythemia even if the normal values are exceeded. The substances that are effective against the nervous symptoms apparently are present in such small quantities that large amounts of liver extract must be administered. There are factors which make it probable that funicular myelitis is an avitaminosis. However, there are only few reports about the therapeutic efficacy of vitamin B when given alone. Stomach preparations are effective against funicular myelitis and should be tried. In especially severe cases they should be given in combination with liver extract.

New Ways of Chemotherapy in Erysipelas. J. Gotlib.—p. 240.

Typhoid Therapy with Neoarsphenamine and Sodium Dehydrocholate.—Wygowski says that there is no specific remedy for typhoid. He divides typhoid therapy into therapy to increase the resistance of the organism, bactericidal therapy, symptomatic therapy and physical therapy. He treated fifty patients ranging in age from 15 to 45 years, forty male and ten female, who usually were admitted to the hospital from one to one and a half weeks after the beginning of their sickness. All the cases were severe and the treatment was administered when there was no contraindication, such as liver, kidney and heart diseases. He used Lucherini and Liuzzo's method of intravenous injection of neoarsphenamine and sodium dehydrocholate. He obtained the following results: Ninety-four per cent of the patients were favorably influenced, showing general improvement and quicker subsidence of symptoms. The duration of the disease was shortened to thirty-two days, while it lasted thirty-nine days in the controls. Complications, such as pneumonia, inflammation of the middle ear and hemorrhage, were reduced to 2 per cent. There were no deaths, while the controls showed a mortality of 6.8 per cent. After recovery no Eberth's bacilli were found in three successive examinations of urine and feces, while there were 12 per cent of typhoid carriers among the controls. After the temperature became normal the blood of the patients treated with neoarsphenamine and sodium dehydrocholate was found to be practically normal. In only one case have symptoms of irritation of the brain cortex been observed, but they subsided spontaneously without leaving after-effects.

Peculiarities of Clinical Course of Primary Cancer of Lung. E. B. Kremerman and T. G. Segal.—p. 1055.

Treatment of Syphilis and Subcutaneous Insufflation of Oxygen.—Rosental and his collaborators consider the fact established that oxygen, when introduced under the skin, will be utilized by the organism and that it will activate the vital processes, neutralize toxic metabolic products and cause their

more rapid elimination. Rosental conceived the idea that by increasing the oxygen content of the tissues of the syphilitic patient he would create unfavorable biologic conditions for the anaerobic spirochetes. Voegtlin and Smith assert that neoarsphenamine solutions increase their parasitotropic effect when acted on by oxygen, but that they at the same time become more toxic to the organism, and they as well as Stühmer and Bering maintain that neoarsphenamine when injected becomes effective after first undergoing oxidation. The authors administered to rabbits infected with syphilis and exhibiting hard chancres half the minimal sterilizing dose of neoarsphenamine, namely, 0.007 cc. per kilogram of body weight, while at the same time introducing subcutaneously from 300 to 500 cc. of oxygen. They were able to demonstrate much more rapid disappearance of the spirochetes than in the control animals, which were given the same dose of neoarsphenamine but not the oxygen. The authors treated 140 patients having primary syphilis with the combined neoarsphenamine, bismuth and oxygen treatment. They have selected patients with pronounced clinical symptoms, large chancres and marked adenopathy. Oxygen was administered from forty to sixty minutes before or after each injection of neoarsphenamine, an average of from twenty to twenty-five oxygen insufflations being given in one course. The time necessary for the complete disappearance of the spirochetes was much shorter than in the controls. The effect on the blood picture and the weight of the patients was a favorable one. All the patients remained seronegative after one course of treatment. The authors feel that the results obtained were superior to those obtained with the old method and that insufflation of oxygen activates the chemotherapeutic properties of neoarsphenamine.

*Dangers of Arteriography. E. Verschuyl.—p. 1007.

*Asthmatic Constitution and Therapy of Bronchial Asthma. A. A. Van der Kroon.—p. 1013.

Dangers of Arteriography.—Verschuyl says that a review of the literature reveals that arteriography may result in various complications. He himself describes two cases. The first patient was a man, aged 70, who was hospitalized on account of an acute attack of severe pain in the right leg, which was pale and cold. The anamnesis revealed that he had had mild attacks of pain in the leg for a number of years. It was suggested that the arterial blood stream had become obstructed as the result of spasm or of embolus. Arteriography was resorted to and it revealed the site of obstruction, but not whether the cause was spasm or embolism. To be sure, the removal of an embolus proved unnecessary, because shortly after the injection of the arteriographic contrast medium, color returned into the leg, the patient could move it again and it felt warm. Nevertheless, the patient died suddenly. The necropsy revealed an extremely large retroperitoneal hematoma and the author thinks that it was the direct result of the puncture of the aorta, which was made for the arteriography. The second patient was a woman, aged 28, who had pain, cyanosis and swelling of the right arm. In order to perform an arteriography, contrast medium was injected into the subclavian artery. Immediately after this injection the patient had a typical epileptic attack, but she finally recovered. The author points out that the literature likewise reports cases of epileptic attacks in the course of angiography. He thinks that, in view of the dangers which are involved, arteriography should be resorted to only as a last resort.

The Asthmatic Constitution.—Van der Kroon shows that a number of factors enter into the development of asthma. The main factor is of a constitutional nature and is designated as asthmatic basis. Under this heading he directs attention to metabolic factors, the sympathetic nervous system, the endocrine equilibrium, dietetic factors, the mineral and water exchanges and so on. Further he discusses the predisposition of the organ, pointing out that the action of nervous stimuli

is dependent on the condition of the organ that responds to them. As regards bronchial asthma, the author stresses the importance of bronchitis. In discussing the treatment of bronchial asthma, he shows how to influence the various factors that play a part in the development of the disorder. He mentions the use of endocrine preparations, dietetic measures and psychotherapeutic treatment. In order to counteract the bronchitis, all disorders of the respiratory tract must be treated.

*Triboulet's Reaction in Localization of Hemorrhages of Digestive Tract. A. Van Meeteren.—p. 1139.

Lead Poisoning in Cigar Makers.—Jordans and his associates observed a large number of cases of lead poisoning among cigar makers. At first they believed that the zinc plate on which the cigar maker cuts the tobacco might be responsible for the lead intoxication, but later it was found that in the region in which most of these cases of lead poisoning occurred the drinking water contained considerable amounts of lead. However, it could not be proved that the lead poisoning of the cigar workers was entirely a drinking-water poisoning. There were indications that occupational factors did play a part. The authors are convinced that the zinc plate with its lead content and the tobacco itself were partly responsible for the lead intoxication. They advise that the zinc plate be eliminated from the process of cigar making.

Triboulet's Reaction.—Van Meeteren points out that Triboulet's reaction is not specific for tuberculosis of the intestine. He reports his experiences with the test on patients with various intestinal disorders. He found that bleeding processes of the intestinal tract can be differentiated in two groups on the basis of Triboulet's test. The first group includes all processes of the upper part of the intestinal tract, that is, the intestinal tract up to and including the duodenum; the second group includes all those in the lower part of the intestinal tract. In the first group the blood that is present in the feces is not detected by Triboulet's test, that is, the test is negative; in the second group it is positive. Thus Triboulet's reaction has differential diagnostic value in the localization of hemorrhages of the digestive tract.

Interesting Case of Blennorrhagic Keratoderma. C. A. Falk.—p. 119.

New Classification of Syphilitic Changes.—Almkvist reviews the early literature of syphilis and points out that Ricord in 1858 arrived at the differentiation of three distinct periods in the development of syphilis. Almkvist says that his own histologic investigations, which have extended over more than twenty years, have led him to doubt Ricord's idea and to arrive at an entirely different conclusion; namely, that the histopathologic changes in syphilis actually represent not different periods, but a uniform state throughout the entire progress of syphilis, modified only by accidental factors. On the basis of his investigations he formulates three general laws for the evolution of the syphilitic lesions: 1. The spirochetes produce in each type of tissue a histologic reaction that is characteristic for the tissue in question but differs from the reaction in other tissues. 2. The changes induced by the syphilitic process in each kind of tissue are of a uniform nature through the entire course of the disease. They are the same in new cases and in

those of long standing. 3. The different clinical manifestations of the syphilitic lesions are the result of such factors as the varying location of the spirochetes, differences in the degree of immunity, toxin-antitoxin reactions and nutritional disturbances. Nevertheless, on the basis of the pathologic conditions the author suggests four instead of Ricord's three periods; namely, (1) initial or humoral syphilis, (2) hematogenous syphilis, (3) serpiginous syphilis and (4) old degenerative syphilis.

Occurrence of Heterogenic Antibodies.—Haxthausen says that heterogenic antibodies are present in most human serums and that recent investigations have shown that F-antigens are extremely prevalent in nature. Several investigators proved that the amount of F-antibodies varies greatly in human serums. Age seems to exert a certain influence, for new-born babies do not possess antibodies at all, but during the first year of life the amount increases and reaches its maximum between the fifth and tenth years. There have been different explanations of this spontaneous appearance of F-antibodies in human serum. One of these considers various infections as the source. In infectious mononucleosis the serum contains especially large quantities of F-agglutinin. F-hemolysins have been observed to increase during pneumonia. High hemolysin and agglutinin titers have been demonstrated in tonsillitis, diphtheria and scarlet fever. This theory of the infectious origin is made even more probable by the fact that F-antigens have been observed in a large number of pathogenic micro-organisms. Nevertheless, infection is doubtless only one of several sources of F-antibody production. Lifeless antigens, such as horse serum, have been proved to have this effect. In order to throw light on the occurrence of F-antibodies in various diseases, the author undertook a series of hemolysin and agglutinin determinations on patients suffering from different skin and venereal diseases, and on a number of control subjects. The tables of the results of the tests indicate that such marked divergence from the normal as exists in mononucleosis was not to be found in any of the different diseases examined. In tuberculosis, syphilis and erythema multiforme the figures are more like those of the controls. In other conditions, however, there is an increase in the hemolysin titer. This was most noticeable in pityriasis rosea, so that it seems possible that in this condition there is an increase of F-hemolysin in the serum. In gonorrhea, eczema, psoriasis and alopecia areata the hemolysin exponents appear to be a little higher than normal. In alopecia areata the agglutination value too seems to be greater than normal. Nevertheless, low titers were observed in several typical cases of the aforementioned disorders. Conditions such as favus, trichophytia and epidermophytia were represented only by one or a few cases, but all these cases showed a high hemolysin titer. One case of Boeck's sarcoid, one case of erysiploid and three cases of inguinal lymphogranuloma showed high hemolysin exponents. Among the eczemas in children there is a distinct difference between the pityriasis simplex group and the allergic group. In the first group the titer is only slightly above the normal, but in the allergic eczemas the hemolysin exponents are extremely high.

*Keratoconjunctivitis Sicca. E. and T. Dalsgaard-Nielsen.—p. 219.

Keratoconjunctivitis Sicca.—The Dalsgaard-Nielsens report seven cases of this relatively rare disease, considered by them as a distinct entity. They state that Sjögren found nineteen cases, all in women, from a polyclinic material of 36,000. In the main the disease occurs in women past the age of 40 and near or during the climacterium; two thirds of the patients have a history of rheumatic fever or signs of changes in the joints, and the general condition is usually inferior for the age. They believe that in cases of keratosis sicca there is a chronic infection which affects the vegetative nervous system, and a resulting hypofunction of certain glands constitutes the basis for the development of the disease.

THE INCIDENCE OF TUBERCULOUS INFECTION IN AMERICAN COLLEGE STUDENTS

DETERMINATION BY STANDARDIZED TUBERCULIN
(PURIFIED PROTEIN DERIVATIVE) ON 18,744
COLLEGE ENTRANTS IN 1935-1936

ESMOND R. LONG, M.D.
AND
FLORENCE B. SEIBERT, PH.D.
PHILADELPHIA

Within recent years great progress has been made in the control of tuberculosis in American college students. Five years ago only a few universities were organized for locating early cases of the disease in the student body. Today throughout the country college health services are better developed, either through well organized full time departments or through part time arrangement with local practicing physicians, and the control of tuberculosis has been made in most instances a major part of the health program.

This emphasis on one disease is the result of general recognition that tuberculosis is one of the most serious causes of disability in those of college age. The sharp upward trend of the tuberculosis mortality curve from the low level of prepuberty years to the high level of early adult life coincides with the age period of the college student. Moreover, it is now generally recognized that although the peak of tuberculosis mortality occurs after the college age, the beginnings of the disease are commonly traceable in the individual cases to the period of the late teens or early twenties.

Thus the colleges are faced at once with a problem and a great opportunity. The problem lies in the susceptibility of the age period and the corresponding relative concentration of disease, and the opportunity in the now well developed large scale methods for early recognition of cases of tuberculosis, permitting prompt arrest of many cases and prevention of serious illness or death. The colleges constitute one of the great filters through which a section of the youth of the nation passes. Seldom after the college age is it so easy to institute mass measures for prevention of the disease.

The importance of mass measures for early diagnosis is evident in the nature of tuberculosis. It is probable that the majority of cases of pulmonary tuberculosis still come to medical attention for the first time when already in an advanced state. It is true that there is no way to find the exact proportion of tuberculosis recorded as minimal when first seen by private physicians. The nearest approach to an estimate can be made through the records of hospitals and sanatoriums for tuberculosis. A survey of tuberculosis hospitals and sana-

toriums in the United States, reported by the American Medical Association¹ in 1935, recorded 13.1 per cent of 66,861 patients as admitted in the minimal stage, and 29.7 and 57.2 per cent respectively as moderately and far advanced. Some of the total admissions represented transfers from other sanatoriums, and doubtless in many cases considerable time had elapsed between first diagnosis and sanatorium entrance. Nevertheless the figures seem significant as an indication of general late diagnosis of tuberculosis, since the current medical trend is to provide institutional care as rapidly as possible for patients found to have this disease.

The reason for the general delayed diagnosis of tuberculosis lies in the fact that its symptoms are trivial in the early stage and commonly not serious enough to urge the patient to seek medical attention. Herein lies the opportunity for the colleges, which control a large body of susceptible youth and can at no great inconvenience to the students subject the whole group to measures for locating all the incipient cases.

The success of an active program for finding the disease, as compared with a passive one in which responsibility is placed on the student to seek medical assistance when he feels he needs it, has been described by numerous physicians from college health services in recent years. Myers and Wulff,² in recording the experience of the University of Minnesota, wrote: "In the early days of our work we had no special organization for finding tuberculosis in the student body. We were so confident that clinical cases of tuberculosis would all present symptoms as early manifestations that we thought it was safe to wait until symptoms appeared."

... We had not then had an opportunity to observe the chests of the same individual over years and see lesions appear and progress to massive proportions without the individual suffering a single symptom." Diehl,³ at the same university, reported that among 2,500 students entering in 1931 a program of tuberculin testing and roentgenographing of positive reactors resulted in the finding of fifteen cases of active tuberculosis of which one was far advanced, five were moderately advanced and nine were minimal. He said, "Had we depended on physical examination and history alone for ordering x-rays of the chest, ten of the fifteen cases would have been missed."

The Tuberculosis Committee of the American Student Health Association⁴ noted that in the year 1934-1935 in seventeen colleges with 85,428 students and an active tuberculosis program the rate for cases discov-

ered was 5.7 per thousand, while in three other colleges, with an enrolment of 13,000 students and without an active tuberculosis program, the rate was only 1.2 cases per thousand, about one fifth as many. The only reason to be assigned for the difference is that in the one group the institutions actively sought out cases, thereby discovering many not sufficiently advanced to cause symptoms, while the other institutions waited for the development of clinical illness and solicitation by the student himself, while incipient symptomless disease remained unknown.

Soper and Wilson⁵ stated that fifteen years of experience has indicated the futility of the old current methods of attack against tuberculosis in detecting early cases. They wrote: "Far too often pathological changes are moderately or far advanced when first discovered, or the symptoms are too few to cause the patient to consult a physician when the disease is still in an

five early cases in the same time in students who had no symptoms. During this period other cases were discovered on the basis of symptoms, but in all these cases the disease was advanced.

The standard case finding program advocated by the Tuberculosis Committee of the American Student Health Association calls for special history forms to elicit evidence of tuberculosis, physical examination and the specific procedure of tuberculin testing the entering students, roentgenographing the positive reactors and reexamining the negative group at intervals. The figures obtained for the incidence of tuberculous infection and the extent of clinical disease in college students are interesting and informative. It is significant that they vary consistently for different parts of the country.

Until recently the tuberculin test has not been on a standardized basis. Aside from real variations in the extent of infection there is variation in the college reports both because of differences in the quality of tuberculin used and because of the employment of different dosages. Variation due to the personal factor in reading reactions is probably of minor importance, as the student health officers in charge of tuberculosis programs in the colleges represent a highly trained group, practicing essentially the same technic. But it has been pointed out recently that variations due to weak tuberculin and the failure to follow with stronger concentrations the negative responses to the weak doses commonly employed for initial tests are responsible for some of the abnormally low incidence of positive reactions reported from some quarters.

Because of this variability, space will not be taken here for review of the several comprehensive reports on the incidence of tuberculous infection in the students of American colleges and universities. Figures range from 12 per cent of 3,000 students reported from the University of Iowa in 1933 to 62 per cent of 3,000 reported from Yale, and 98 per cent of senior medical students reported by Hetherington, McPhedran, Landis and Opie in the University of Pennsylvania. Details can be found in the papers already cited.

The reports are equally variable on the incidence of clinical disease in the colleges with tuberculosis programs. Ferguson⁸ as chairman of the Tuberculosis Committee of the American Student Health Association has summarized the reports from time to time in his annual reports to the association. In 1933 the highest case incidence was 13.7 cases per thousand for men and 12.7 for women, while the lowest case incidence for both men and women was 3.1 per thousand. The average for the group surveyed was 6.4 cases per thousand in men and 7.5 cases in women, a sex difference corresponding more closely to the difference in tuberculosis mortality in the two sexes at the age period concerned. In this connection it may be noted that Cunningham⁹ at the University of California called attention to a preponderance of cases in women in the age period 18-23 years.

The thorough study of Stiehm at the University of Wisconsin is enlightening and may be looked on as representative of a large section of the country. During the year 1933-1934 2,412 students were tested with tuberculin. Thirty per cent reacted positively. The positive reactors were roentgenographed. In approximately 5 per cent of them, or 1.5 per cent of all the students, roentgenologic examination revealed adult-

early stage." In their own experience at Yale University they found that an active case finding program based on mass tuberculin testing and x-ray examination in the two years of 1930-1932 brought to light more cases (forty-three) than were found in the preceding ten years (thirty-eight) by routine history and physical examination alone.

At the University of Wisconsin, Stiehm⁶ recorded an increase of 430 per cent above a previous fourteen year average, after the institution of a definite program for discovering cases of tuberculosis in the student body. In a discussion of the procedure at Stanford University, Shepard⁷ noted that a general program encouraging students to report symptoms brought to light only three early cases in two years, and two of them with the serious complication of hemorrhage, while a standard tuberculin-x-ray program discovered

type tuberculous infiltration. In nearly one fifth of these, i. e., about 1 per cent of the positive reactors and 0.2 per cent of all the students tested, the disease discovered was serious enough to require sanatorium care.

Aside from the differences due to sex, characteristic variations according to age and course of college study have been discovered. Soper and Wilson in the students

entering Yale in 1931 found an incidence of positive tuberculin reactors of 53.5 per cent in undergraduates at an average age of 18 years and 8 months, and 67.7 per cent in graduate students, who averaged 24 years and 6 months in age. Among the graduates were students in the various professions. The rate of infection of entering graduate students ranged from 57.8 per cent among law students to 76.9 per cent in medical students. The variation in the amount of clinical tuberculosis uncovered was parallel. Stiehm studied the rate of increase in infection with the passage of time at the University of Wisconsin. Four hundred and eighty-five students who were negative to tuberculin in the fall of 1933 were retested eighteen months later. Forty-five, or 9.3 per cent, had become positive to tuberculin.

TESTS IN AMERICAN COLLEGES IN 1935-1936

Observations such as the last cited have maximum significance when the tuberculin used is standard and of unvarying strength. When two different tuberculins are used, such a result is of much less significance. So, too, when different samples of tuberculin are used in the various surveys throughout the country the epidemiologic importance of the results obtained is uncertain. On the other hand, when surveys are made in different parts of the country and on students of varying background and are continued over a period of years, and a tuberculin of unvarying strength is employed, with constant technic, the results are of great importance for general epidemiologic understanding.

The only surely uniform tuberculin for testing purposes is the active principle itself, in solutions of standard concentration. In the purified protein derivative of tuberculin described in 1934¹⁰ we believe the active

principle of tuberculin has been secured in reproducible and practically pure form. This tuberculin was first used in colleges in the fall of 1934, and the results in 8,328 students in eleven colleges were reported to the American Student Health Association in December of that year.¹¹ The colleges for the most part drew their students from the general region of their own location. A definite variation in the rate of infection in different sections of the country was shown. The rate on the Atlantic seaboard was relatively high, that in the Middle West relatively low, and that for the West Coast fairly high again.

In order to collect more figures as well as to assist in the promotion of college tuberculosis programs, an offer was made by the Henry Phipps Institute in the summer of 1935, before the College Hygiene Association and the American Student Health Association, to furnish purified protein derivative without cost to those colleges or universities carrying out at least 500 complete tests, using the regulation dose of 0.00002 mg. for the first test and a second dose of 0.005 mg. on those failing to react to the first injection, and finally sending their results to the Institute for compilation. Two biological supply houses, which have cooperated with the National Tuberculosis Association in its research program,¹² cooperated again by contributing to the Henry Phipps Institute considerable amounts of purified protein derivative for incorporation in standard solution for distribution. The material was sent out to the student health services in the colleges in 1 per cent solution, which has been found to be perfectly stable. Instructions were furnished for making such dilutions that 0.1 cc. furnished 0.00002 mg. and 0.005 mg. doses. Record forms were also sent. It was requested that all

unused dilution be discarded at the end of the day. Those colleges practicing mass testing of from 100 to 500 students a day used the material very economically, while in others, in which only a few tests were made each day, there was considerable waste.

The results of 18,744 tests were returned for analysis. They are summarized in the accompanying tables. In almost all cases the tests were complete, the results of

the second dose being recorded for those failing to react to the second dose. In about 5 per cent of cases, however, students did not return to have the second tests read. In this small number of cases mathematical correction was made by computing as positive among this group the same proportion as were found to be positive among those who did return for the reading of their second test.

Variation on a geographic basis is at once apparent from table 1. The results for the academic year 1935-1936 confirm our previous report covering the year 1934-1935. A high rate was found in the East, a lower rate in the Central states, and a relatively high but inconstant rate on the Pacific Coast. A noteworthy contrast is observed between Idaho, with a very low rate, and New Mexico, with the highest rates seen in the country.

Secondly, definite variation by sex can be seen from comparison of tables 2 and 3. Where the average age for the two sexes is greatly different, significant comparisons obviously cannot be made. However, the difference is well brought out by comparison of certain universities in which the age levels for the sexes are comparable. The universities of Pennsylvania, Wisconsin, Kansas and California may be cited as examples, representing the eastern, central and western sections of the country. Of the Pennsylvania men, with an average age of 18.9 years, 48.8 per cent were positive to tuberculin, while of the women, averaging 18.5 years, 42.9 per cent were positive. More significance could be attached to these figures if the number of women examined (184) were higher. The numbers at the other three institutions were statistically significant, however. At Wisconsin, of 2,123 men averaging 19 years, 30.8 per cent were positive to tuberculin, while of 1,128 women averaging 19.4 years, only 24.6 per cent were positive. At Kansas, of 912 men averaging 19.3 years of age, 35.1 per cent were positive as compared with 25.3 per cent of 396 women, whose average age was 19.1 years. At California (Berkeley) the figures were: 1,259 men, average age 17.4 years, 33.6 per cent positive to tuberculin; 1,041 women, average age 17.4 years, 29 per cent positive. The figures for Stanford University are similar to those from Berkeley except that the age of the students is greater and the rate for both sexes correspondingly higher. The figures for Stanford University were: 708 men, averaging 19.8 years, 45 per cent positive; 325 women, averaging 19.6 years, 30.7 per cent positive.

This sex difference did not always obtain, however. At Oregon, for example, where the sexes were equally represented of the same age, no significant difference was found. At other institutions such as Yale and Pennsylvania State University, where the entering women were on the average considerably older than the men, their infection incidence, as measured by the tuberculin test, was appreciably higher than that of the men.

RESULTS

The geographic variation, which now seems established,¹³ is probably a reflection of the level of tuberculous infection in the community concerned. Objection might be made to this view on the ground that the college students at one institution do not necessarily represent the geographic location of the college, since they might have come from any part of the country. However, correspondence with the administrative offi-

cers of the colleges brought out the fact that with a few exceptions the majority of students were indeed of the general region in which the college was situated.¹⁴ In the state universities the representation was almost entirely from the same state. It is interesting to note in this connection that a group of students at one university, but themselves from distant regions, may bring the rate characteristic of the distant regions with them. Stiehm¹⁵ found for the two years 1933-1935 a rate of 26.1 per cent for residents of Wisconsin at the University of Wisconsin and the much higher rate of 46 per cent for residents of eastern states attending Wisconsin.

The objection that college students are not necessarily representative of their region because they are a minority selected from a certain social and economic level is reasonable. It can only be said that college attendance today is by no means restricted to the upper social and economic levels. This fact is especially apparent in the state universities. In any event no claim is made that the college figure is the figure for the corresponding age in the population of the region concerned. We do feel, however, that it reflects the figure for the general population in about the same way in the different regions.

The high rate for the East is usually attributed, and with probable correctness, to the higher density of population in the eastern region, imposing more frequent contact and in the long run more exposure to tuberculosis. The mortality in the more crowded regions is known to be in general higher than in the less crowded, and presumably morbidity and chance for further spread of infection correspond to the greater mortality.

Conversely the relatively low rate in the Middle West can be explained on the basis of emanation of the students from less crowded regions of lower tuberculosis morbidity. The relatively high rates for the West Coast offer a problem. In part, at least, they may be attributed to the fact that for several decades the West Coast has received an immigration of tuberculous patients who have settled and raised their families there. Doubtless a good deal of community spread of infection has occurred from this immigration. In favor of this hypothesis is the high rate in the University of California at Los Angeles, notable in comparison with the rate in the University of California at Berkeley. To be sure the figures for the southern group are small and the age incidence is higher, but the disparity in rate of infection is so great as to suggest a significant difference, and it seems plausible to attribute the high rate in the southern institution to the resort character of southern California.¹⁵

14. At Yale University 71 per cent of the students tested were reported as from New England and the Middle Atlantic states. Eighty-two per cent of the tested students at the University of Pennsylvania came from less than 200 miles of Philadelphia. Approximately 70 per cent of the students at Bryn Mawr came from the North Atlantic states. Haverford students were described as "chiefly from eastern Pennsylvania and New Jersey." Eighty-four per cent of tested students at the University of Wisconsin were residents of the state. Those tested at Iowa were listed as "mostly from Iowa." At the University of Kansas 80 per cent of those tested were from the state and 95 per cent from Kansas or states immediately adjoining. At the University of New Mexico the situation was somewhat different, 42 per cent listed as natives while a considerable number were recent immigrants from the East. Among the latter group were numerous members of health-seeker families. Ninety per cent of the students tested at the University of Oregon were from the state and 98 per cent from Oregon or contiguous states. Of 2,900 students registered at San Jose State Teachers College in California only fourteen were from outside the state. Of the students tested at Stanford University, 74 per cent were from the state of California.

15. Dr. MacKinnon has written the authors that the rate for entrance for the year 1936-1937 is about 13 per cent lower than for the previous year.

However, this leaves the high rate for the University of Oregon still to be explained, and no explanation is offered at present.

The contrast between the Idaho schools in the Northwest and the New Mexico schools in the Southwest is almost certainly to be explained on the basis of the number of tuberculous families in the two regions and relative abundance of opportunity for contact. Shepard⁷ reported a communication from Dr. Halvorsen of the University of Idaho to the effect that almost no students from the rural districts of Idaho react to tuberculin, while those from the mining districts of southern Idaho are apt to be positive reactors. New Mexico, on the other hand, has long been a resort for the tuberculous, and it seems inevitable that this fact would be reflected in the incidence of infection among students at the state university. Miss Ruth Connely, executive secretary of the New Mexico Tuberculosis Association, has communicated to us a fact interesting in this connection. In an extensive survey to determine the incidence of positive reactors to tuberculin in the schools of Albuquerque, a relatively low percentage of reactors was found in a large group of Spanish descent as compared with an equally large number of American ancestry. The former group came to school from mountain districts where their ancestors, original Spanish immigrants, had settled nearly three centuries before, while the group of American ancestry to a considerable extent were made up of children of health seekers who had come directly to take up residence in the urban centers of the state, such as Silver City and Albuquerque.

The higher incidence of infection in entering college men than entering women noted in this study conforms with the figures given by Ferguson,⁴ who reported to the American Student Health Association that in the three years 1932-1935 lower figures for women than for men were recorded each year for the group of colleges reporting. It is an established fact that the mortality from tuberculosis is higher in young women than young men, and from this a corresponding morbidity might be argued. But this offers no evidence as to the mere incidence of infection, which is dependent on home and subsequent more casual contact. There is some reason to believe that, while the home contacts for the two sexes are approximately the same, boys are less restricted in their contacts outside the home and therefore have a greater opportunity for chance infection.

SUMMARY

1. During the academic years 1934-1936 statistics were gathered from American colleges using the standardized tuberculin adopted by the Committee on Medical Research of the National Tuberculosis Association; namely, purified protein derivative tuberculin.

2. The results for 18,744 students, chiefly new entrants, in twenty colleges reporting in the year 1935-1936 represent accurately completed tuberculin tests in which a strong standard dose of purified protein derivative was administered to all negative reactors to an initial small standard dose.

3. A geographic variation in the incidence of tuberculous infection was found, with relatively high rates (from 40 to 60 per cent) in the East and Far West and low rates (from 20 to 30 per cent) in the Central states. Since the majority of the students in the colleges reporting were residents of the general region of their college, the figures are believed to reflect the incidence of tuberculous infection in the populations of

those regions. Excessive rates were found in regions noted as resorts for tuberculous patients.

4. In colleges reporting tests on large groups of young men and women of approximately the same average age, the rate of positive tuberculin reaction was higher in men than in women.

THE USE OF BENZEDRINE SULFATE IN POSTENCEPHALITIC PARK- INSON'S DISEASE

PHILIP SOLOMON, M.D.

PROVIDENCE, R. I.

ROGER S. MITCHELL, M.D.

GLENS FALLS, N. Y.

AND

MYRON PRINZMETAL, M.D.

LOS ANGELES

In 1933, when benzedrine (beta-phenylisopropylamine) sulfate was first used in the treatment of narcolepsy,¹ it was noticed that the patients being treated not only stopped having their attacks but also reported that they tired less easily and felt more energetic in general. It was therefore thought advisable to experiment with benzedrine sulfate in conditions in which asthenia is a prominent symptom.

Twenty-eight patients with postencephalitic Parkinson's disease, ten patients with arteriosclerotic Parkinson's disease and twenty-two patients with psychoneurosis have been given benzedrine sulfate for periods varying from four weeks to sixteen months. The oldest patient in the postencephalitic group was 54, the youngest 15, with the average age 32. A history of encephalitis was definite in seventeen patients, was probable in four and could not be obtained in seven. The clinical picture was characteristic in every case, though the following signs varied from patient to patient: rigidity of the neck, trunk and extremities; loss of associated movements; tremor of the head, body or extremities; masklike facies, with slowness or absence of emotional expression; monotonous voice; slurred speech; loss of postural reflexes; oculogyric crises; increased salivation; oily skin; impairment of sleep mechanism (somnia by day and insomnia by night); weakness, and easy fatigability and lack of "energy" (often complete inability to work).

All the postencephalitic patients were tried on benzedrine (benzedrine sulfate) alone; twenty-one were given scopolamine or stramonium alone, and, in addition, these drugs in combination with benzedrine in various doses. Twelve patients were tried on ephedrine sulfate (from three-eighths to three-fourths grain [0.024 to 0.048 Gm.] three times a day) alone and in combination with scopolamine or stramonium in order to compare the effectiveness of benzedrine with ephedrine. An effort was made to determine the regimen on which each patient felt the greatest benefit. The arteriosclerotic group was given benzedrine alone, scopolamine alone and the two in various combinations. The psychoneurotic group was given benzedrine alone.

From the Departments of Neurology and Psychiatry, Massachusetts General Hospital; Neurological Unit, Thorndike Memorial Laboratory, and the Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Departments of Neuropathology and Medicine, Harvard Medical School.

1. Prinzmetal, Myron, and Bloomberg, Wilfred: The Use of Benzedrine for the Treatment of Narcolepsy, *J. A. M. A.* 105:2051 (Dec. 21) 1935.

Since the evaluation of the results depended largely on the subjective accounts of the patients, efforts were made to reduce the effect of suggestion to a minimum. The patients were told that they were to try a new medicine which might not help them but could do them no harm. They were not told in what direction improvement might be expected; they were told, in addition, that some of the medicine might have no effect; finally they were urged to be very critical of any change since, if the medicine had no effect, there were other medicines and combinations that we then wished to try. In nineteen of twenty-eight cases the results were controlled by the substitution of blank pills, exactly similar in taste and appearance to the active pills, without the patient being informed of the change.

* + indicates improvement; 0, no change; .., symptoms not present.

On each visit the patient was first allowed to make a spontaneous general report as to whether he was better, the same or worse and what the changes were; he was then asked specifically about feeling of energy and well being, drowsiness, strength, tremor, rigidity, oculogyric crises and ability to work. Untoward effects were reported. The general appearance of the patient, the facial expression, the manner of speaking and the performance of ordinary muscular movements were observed and compared on each visit. These observations were found to tally closely with the patients' subjective feelings.

RESULTS

In Postencephalitic Parkinson's Disease.—Beneficial effects from benzedrine alone, or from the addition of benzedrine to scopolamine or stramonium, were reported by twenty-six (93 per cent) of the twenty-eight patients in this group (table 1; only cases 12 and 13 failed to show improvement). The most uniform result was that of a feeling of increased energy and well being. This was remarked in twenty-five of the twenty-six cases in

which lack of energy was a symptom, though expressed variously: "more pep," "more energy," "I feel more like doing things." Drowsiness and the necessity for frequent naps during the day was also eliminated completely in twenty-three of the twenty-four patients in whom these symptoms were found.

The following further reports were made: Twenty-two were able to do more work. One young man who had been practically helpless was able to get a job driving a truck; several women were able to resume their housework. Twenty patients observed a decrease in their muscular rigidity. Nineteen of the patients said they felt stronger. Seven patients observed a decrease or disappearance of their tremor, while nine noticed no change in tremor; the other twelve did not have tremor.

There were eight patients in the group who had frequent oculogyric crises. Scopolamine and stramonium had been effective in reducing the number of these attacks but had not succeeded in eliminating them. With the addition of benzedrine therapy the attacks completely disappeared in six patients, while their frequency and severity were greatly diminished in the other two; they recurred only when blanks were substituted for the active pills, the substitution being made in four cases. When given alone, benzedrine abolished the attacks of only two but reduced the frequency in the other six.

In every instance in which blank pills were given the next report of the patients indicated that the beneficial effects they had previously noticed had now disappeared. The manner of the reports varied considerably. Most of the patients came in discouraged, saying that the new medicine was no good after all, that perhaps its effects had worn off, that they might have acquired a tolerance for it. They related in detail all the original symptoms that had recurred. Two patients after being given blanks did not return to the clinic at all and had to be sent for. Five patients guessed that they had been given inactive pills as a test. Two said that, while they did not feel quite as bad as they did when they first came in, most of the improvement was gone.

It is of interest that of the two patients who had no improvement from benzedrine sulfate one had severe thalamic pain and the other complained only of tremor and slight rigidity.

Improvement was noted in only fifteen (53.6 per cent) of the twenty-eight patients when benzedrine was used alone; in two of these the improvement was felt to be equal to the effect from the combination of benzedrine with scopolamine or stramonium; in both of these cases, lack of energy and drowsiness were the outstanding symptoms.

Of the twelve patients on whom ephedrine was used alone, ten definitely felt no beneficial effect; that is, their symptoms grew worse. One felt that ephedrine was as effective as benzedrine and one could not be sure. Of the twelve patients on whom ephedrine plus scopolamine was used, seven were worse, two felt a slight benefit, and three felt as much benefit as on benzedrine therapy. These three were among the mildest cases in the group. Table 2 shows a graphic comparison of the beneficial effect of the various medications used in these cases.

Objectively, brief tests of muscular rigidity and strength were made on twelve patients. With regard to the degree of tremor, no reliable method for objective comparison was available, so that the patients' subjective

tive account had to be accepted. Timing for ten-second periods of the rapidity of complete flexion and extension of the arm at the elbow, also pronation and supination of the hand and forearm, were used to measure rigidity. Improvement as shown by the tests was considered definite only when the rapidity of movement was at least doubled during the test period. A simple spring dynamometer was used to test the strength of the grip. The best of three efforts was taken each time as the result of this part of the test.

The results of these tests were as follows: One patient out of five who were tested showed definite decrease in rigidity on benzedrine alone, while three out of these five showed definite improvement on scopolamine alone. When benzedrine and scopolamine were used in combination, of the seven who were tested, definite improvement could be demonstrated only in the four who benefited from scopolamine or benzedrine alone. There was no definite increase in strength in four patients on benzedrine alone or on scopolamine alone; two out of seven patients on benzedrine and scopolamine together, however, did show definite increase in strength. In other words, benzedrine had little objective effect on rigidity or strength, whereas scopolamine or stramonium was more effective in combating rigidity while equally ineffective in improving strength.

Five of the patients who received ephedrine were tested in the same manner: there was definite improvement similar to that obtained with benzedrine therapy in one; ephedrine plus scopolamine led to definite improvement in two, the same two that showed definite improvement on benzedrine and scopolamine; from the objective standpoint, therefore, benzedrine and ephedrine were similar in their failure to produce definite objective improvement in muscular strength and rigidity in the majority of cases.

In Arteriosclerotic Parkinson's Disease.—Benzedrine was given to ten patients with the arteriosclerotic type of Parkinson's disease. The ages of these patients varied from 58 to 76, the average age being 70. The chief complaints were coarse tremor of the extremities, muscular rigidity and, in contradistinction to the postencephalitic group, a degree of mental agitation which in two was extreme. The results were as follows: Six were worse, three remained unchanged and one felt better. When benzedrine was added to scopolamine or stramonium, of six patients two felt worse, three were unchanged and one felt better. The one patient who felt better in each instance had only very mild symptoms and was benefited also by blanks. Of the nine patients who were not helped by benzedrine, seven were helped by scopolamine while the other two were not helped by any medication. The untoward effects noted in the six who were made worse by benzedrine were insomnia in all six, restlessness and irritability in four, increased tremor in three, anorexia in three, and nausea and vomiting in two.

In Psychoneurosis.—Benzedrine sulfate was given to twenty-two selected patients with various forms of psychoneurosis in whom the chief complaints were also lack of energy, drowsiness, weakness and easy fatigue. Most of these patients were seen concurrently with the postencephalitic group. The procedure used in the two groups was identical. Yet in only two (9 per cent) of the psychoneurotic patients was there definite subjective improvement in asthenic symptoms as contrasted with

the improvement noted in 93 per cent of the postencephalitic group. This improvement was controlled by the substitution of blank pills in the patients who were benefited by benzedrine.

DOSAGE

The usual maintenance dose of benzedrine sulfate was from 10 to 20 mg. taken orally two or three times a day.² In one patient 5 mg. twice a day was the optimum dose. As much as 160 mg. a day for three weeks was taken by one patient without apparent harmful effect. We usually started with 5 or 10 mg. before breakfast and lunch and increased the dose gradually until the maximum therapeutic effect was obtained.

* The number of +'s indicates the relative degree of improvement; ±, doubtful improvement; 0, no improvement.

Scopolamine hydrobromide from $\frac{1}{200}$ to $\frac{1}{100}$ grain (0.3 to 0.6 mg.) or stramonium leaves $2\frac{1}{2}$ to 5 grains (0.16 to 0.32 Gm.) were given two or three times a day, both alone and in combination with benzedrine in most cases, in an attempt to determine the most effective regimen.

The duration of action of an individual dose of benzedrine varied from three to seven hours, though most patients reported that beneficial effects began to wear off in four or five hours. Patients, particularly those with oculogyric crises, felt the effect of benzedrine come on in from fifteen to twenty minutes.

UNTOWARD EFFECTS

Transient untoward effects were noticed by twelve (43 per cent) of the postencephalitic patients. Eleven

2. All the benzedrine sulfate and other medication used, together with the blank pills, were furnished by Smith, Kline & French Laboratories, Philadelphia.

commented that they did not sleep well the first few nights following the beginning of treatment. The relative insomnia usually lasted no more than three days and usually wore off without the necessity of reducing the dosage of benzedrine. It was possible to eliminate this untoward action in most cases by starting the benzedrine slowly: 10 mg. on arising the first day with no further treatment that day, and 10 mg. morning and noon the next day, the dosage being increased thereafter as indicated. Evening doses were not given except in instances when patients did not wish to go to sleep until late. Dizziness or light headedness and a feeling of undue nervous tension appeared for a day or two at the beginning of the treatment in six cases and recurred temporarily when the dosage was increased later in three. Excessive restlessness and excitement occurred temporarily in two cases. These symptoms occurred on 20 mg. of benzedrine a day in one and on 40 mg. a day in the other and were eliminated by halving the dose in each case. Later the symptoms did not reappear when the dosage was raised to 30 mg. a day in each case. Nausea, anorexia and vomiting occurred on the first day of treatment in one case. Four patients noticed that their mouths and tongues were drier than usual while taking benzedrine.

It is interesting to mention here that two of our male patients, who had not taken scopolamine or other depressant drugs, reported that benzedrine sulfate produced in them an increase in sexual potency.

The effect of benzedrine on three other patients not otherwise included in this paper should be mentioned here. Two of these were women with involutional melancholia in whom asthenia was prominent among a great variety of other symptoms. Following the first few doses of the drug, both these patients became much worse generally, complained more about their symptoms and were so obviously agitated that commitment became necessary. The benzedrine apparently influenced the symptomatology of the psychosis, precipitating an active phase in place of the former depression in these two individuals. The third patient, a man aged 26, had been seen by a number of neurologists and psychiatrists because of peculiar "spells" and because of maladjustment and personality difficulties following an attack of probable encephalitis. A presumptive diagnosis of narcolepsy was made and the patient did fairly well on ephedrine for a time. When he changed to benzedrine he at first was much improved. When the dosage was raised from 40 to 60 mg. a day paranoid ideas and auditory hallucinations developed for the first time and the patient had to be hospitalized.

Thus far we have seen no evidence to indicate either an increasing tolerance to the drug or habit formation. Several patients who had taken the drug for six months or more were asked how they felt when it was withdrawn for periods up to three weeks; they all said their unpleasant symptoms returned and they felt worse, but not worse than they felt before ever taking the drug. The first patient with narcolepsy reported by Prinzmetal and Bloomberg¹ is still taking the same dose after three years. The possibilities of habit formation or of late untoward effects are, however, not conclusively ruled out by these observations or by others published to date. For this reason and because of the untoward effects that have been noted, the indiscriminate use of benzedrine is undesirable.

SUMMARY

The effect of benzedrine (beta-phenylisopropylamine) sulfate was studied in twenty-eight patients with postencephalitic Parkinson's disease. The dose varied from 10 to 160 mg. orally per day, either alone or in combination with scopolamine or stramonium. The study was controlled by the substitution of blank pills in nineteen of the patients and by the administration of benzedrine to a group of twenty-two psychoneurotic patients, all of whom complained chiefly of asthenia similar to the patients with postencephalitic Parkinson's disease. The effect of ephedrine was compared with benzedrine in ten patients. Benzedrine sulfate was tried in ten patients with arteriosclerotic Parkinson's disease.

The results in the postencephalitic group, which signify benefit derived from benzedrine alone or from the addition of benzedrine to an adequate scopolamine or stramonium regimen, were as follows: There was subjectively increasing energy in twenty-five out of twenty-six patients (those who complained of lack of energy), 96 per cent; disappearance of drowsiness in twenty-three out of twenty-four, 95 per cent; increased feeling of strength in nineteen out of twenty-six, 73 per cent; decreased or abolished tremor in seven out of fifteen, 44 per cent; subjectively decreased muscular rigidity in twenty out of twenty-six, 77 per cent; disappearance of oculogyric crises in six of the eight patients who had this symptom, and greatly diminished frequency and severity of the symptom in the other two, and increased ability to work in twenty-two cases, 79 per cent.

Benzedrine alone was beneficial in fifteen cases, 53.6 per cent, but this effect was equal to the effect of the combination with scopolamine or stramonium in only two cases, 7 per cent. In all, twenty-six of the twenty-eight patients (93 per cent) showed definite improvement directly traceable to benzedrine. In every instance, when blank pills were substituted for benzedrine, beneficial effects were no longer reported and the original symptoms returned. Ephedrine alone was effective in one out of twelve cases; the addition of ephedrine to scopolamine or stramonium caused improvement in five out of twelve, but this improvement was equal to the benefit derived by adding benzedrine to scopolamine or stramonium in only three.

As to the results of the objective tests, rigidity was demonstrably decreased in a number of cases by the use of scopolamine or stramonium, while benzedrine and ephedrine were much less effective. There was no consistent increase in strength from any of the modifications used.

None of the ten patients in the arteriosclerotic group were benefited by benzedrine, while untoward symptoms appeared in six. In the psychoneurotic group only two patients out of twenty-two, 9 per cent, seemed to be benefited by benzedrine.

CONCLUSIONS

1. Benzedrine sulfate is a useful drug in the symptomatic treatment of postencephalitic Parkinson's disease.

2. Used alone, benzedrine sulfate is effective in this condition when symptoms of drowsiness and lack of energy predominate, but usually it is most effective when used in combination with scopolamine or stramonium.

3. Although improvement in muscular rigidity and strength from the use of benzedrine sulfate was not

conclusively demonstrated by means of objective tests, these symptoms were subjectively improved in more than 70 per cent of the cases.

4. Benzedrine sulfate seems to act almost specifically in abolishing or reducing the number and severity of oculogyric crises.

5. Benzedrine sulfate was of no value in ten cases of arteriosclerotic Parkinson's disease.

6. Benzedrine sulfate was of no value in twenty out of twenty-two cases of psychoneurosis with asthenia as a prominent symptom. In both this group and the group presenting arteriosclerotic Parkinson's disease, untoward effects frequently developed.

7. Benzedrine sulfate apparently has a greater stimulating action on the central nervous system than ephedrine.

8. Until more is known about the action of this drug, it should be used with caution.

REPORT OF CASES

CASE 3.—Mrs. E. J., aged 42, a housewife, had encephalitis in 1919. In 1932 she first noticed tremor of the left arm and generalized muscular rigidity.

When seen, April 3, 1934, her presenting complaints were of feeling "tired," "dopey-like," having "no energy at all," and inability to do her housework. On examination it was noticed that the patient's voice was dull and monotonous and that she stared fixedly. There was generalized muscular rigidity, cog-wheel in character, greater on the left side. There was a rhythmic coarse tremor of the left hand and arm. Postural reflexes were markedly impaired and there was a loss of associated movements.

The patient was given 10 mg. of benzedrine sulfate, morning and noon, and on April 5 she reported: "My nerves are more quiet," "I don't shake so much," "I don't feel quite so tired as I did." She said that her sleepiness during the daytime had entirely disappeared but that she also noticed that she had not slept well at night. The benzedrine sulfate was continued and the morning dose was increased to 20 mg.

April 10 the patient reported "I'm getting along fine now. The medicine makes me feel much better. I don't feel sleepy and dopey the way I used to. I don't shake half as much as I did, and I'm not so stiff." She added that she was now doing all her own housework, including the washing. The other day she had even cleaned the stove—"something I haven't done for years." Her sleeping at night was back to normal. It was the impression of the examiner that the patient looked much brighter and livelier and talked with more inflection in her voice. She was given benzedrine in solution in the same dosage.

April 15 she reported that the liquid medicine was exactly the same as the pills. All the beneficial effects had continued. She was now given blank pills without being told of the change.

April 22 the patient reported: "These pills had no effect at all. I stopped after taking them twice. I feel the same now as before I came to you." She was given the active pills again.

April 29 she said she "noticed the difference right away." All her improvement had come back again. She was even able to wash the floor.

CASE 8.—J. S., a single, unemployed man, aged 22, had noticed stiffness, tremor and some clumsiness especially of the left arm and leg for three or four years. He remembered having diplopia for one day in 1919; other evidence pointing to encephalitis was lacking.

When first seen, Jan. 9, 1936, he complained chiefly of lack of energy, easy fatigue and "tapping" of the left foot. He had a monotonous, rather explosive manner of speaking, masklike face, with cog-wheel rigidity and rhythmic coarse tremor of all the extremities.

He was given 10 mg. of benzedrine sulfate morning and noon. He reported, January 27, that he felt very much better with "more pep and less shakes," and asked for more of the new medicine. He was given blanks. The day following he returned saying "I had no effect at all after the last pills." He was given active pills and except for infrequent insomnia and tremor he got along quite well. May 4 he reported feeling rather poorly, having lost weight. He was given 25 mg. of

benzedrine sulfate and stramonium leaves $2\frac{1}{2}$ grains (0.16 Gm.) three times a day. In a week he noticed improvement in all his symptoms, saying "I haven't felt better in a long time." Blanks were then substituted for the benzedrine sulfate and he returned May 16 feeling very drowsy and tired out and with a marked speech defect. Resumption of active pills allayed these symptoms; omission of the stramonium May 27 was followed in a few days by some exacerbation of rigidity and tremor but not any of the more subjective symptoms.

When last seen, again on the combined medication, he had gained 10 pounds (4.5 Kg.) and had been doing some carpentering about his home, which he had previously been unable to do.

CASE 11.—G. F., an unemployed man, aged 30, without any direct or indirect history of encephalitis, began at the age of 16 to have tremor and rigidity, first in the right hand, then in the left, and finally in the legs. His speech became slurred and difficult and finally he began to have oculogyric crises, which were now occurring four or five times a week, whenever he "got excited" or used his eyes too much.

When seen Feb. 4, 1936, physical examination revealed tremor and rigidity of all extremities, more on the left side, markedly impaired postural reflexes and associated movements, mumbling, monotonous, almost unintelligible, speech, marked salivation with drooling at the mouth, and an almost constant fluttering of the eyelids. He was taken off the tincture of stramonium (from 60 to 100 minims [3.6 to 6 cc.] three times a day), which he had been taking, and was given 10 mg. of benzedrine sulfate twice a day; he returned in four days saying that he felt worse, though he seemed more alert to the examiner.

He was then put on stramonium leaves $2\frac{1}{2}$ grains (0.16 Gm.) plus 5 mg. of benzedrine sulfate three times a day. He returned in two weeks and said that he felt fine. He had much more energy, had been able to play baseball and, most striking of all, had had only one oculogyric crisis, despite the fact that he had been "excited" several times and had done a good deal of reading.

The following week he caught cold and his symptoms returned. The dose of benzedrine was then doubled and for the next two months he felt quite well. During this entire period he had only one mild oculogyric crisis, and that accompanied a severely upset stomach following the Passover feast. He played tennis and baseball; his speech became intelligible, a fact remarked on by his friends; he no longer felt like sleeping during the day; his tremor and rigidity also seemed decreased.

May 12, blanks were substituted for the benzedrine, the stramonium being continued. He returned May 19 saying—and looking as if—he had slowed up in every way; he had become "nervous and stiff" and had had three oculogyric crises. Ten milligrams of benzedrine sulfate intramuscularly had no effect after an hour on the oculogyric crisis he was having at the time. On resumption of the active pills, however, he straightened out as before and has had no further oculogyric crises to date.

CASE 18.—J. E., an unemployed man, aged 29, had encephalitis in 1918. About ten years later he began to notice that his movements were slower than normal. About five years ago his eyelids first began to "flicker" uncontrollably and finally he began to have oculogyric crises. He had taken scopolamine for seven years off and on, as much as sixteen $\frac{1}{400}$ grain (0.00065 Gm.) pills a day. He had noted that it usually helped to control the oculogyric crises.

When we saw him for the first time, Feb. 10, 1936, he complained chiefly, in addition to his eyes, of slowness of thoughts and action: "I have to think of every movement I make—I can't seem to make any unconscious movements at all." He had never noticed tremor or rigidity. Physically he was in good general condition and seemed normal in every way except for a blank, expressionless face, glassy wide-open eyes, monotonous jerky speech, and an avoidance of all unnecessary movements.

He was given 10 mg. of benzedrine sulfate twice a day in addition to the eight or nine scopolamine $\frac{1}{400}$ grain pills that he had been taking. Drowsiness, slowness and indecision were greatly improved and oculogyric crises were entirely abolished for about three weeks. Blanks were then substituted for the benzedrine and the patient returned in two days with recurrence of all the presenting symptoms, especially the oculogyric crises. Benzedrine was resumed and these symptoms disappeared. A few weeks later a brief omission of scopolamine

with the patient's knowledge, was attended by temporary reappearance of severe eye symptoms.

CASE 22.—Miss C. M., aged 34, unemployed, complained of marked rigidity and slight tremor of all extremities, lack of energy, drowsiness, general asthenia, anorexia and oculogyric crises occurring about two or three times a week. Her symptoms began at the age of 14 years and had become somewhat worse in recent years. There was no history of encephalitis.

When seen, April 24, 1936, her posture was rigid with the head thrust forward, and the arms and legs revealed considerable rigidity of the cog-wheel type on passive movement; she had a masklike facies, a monotonous voice, and increased deep tendon reflexes; otherwise the physical examination was negative. She had taken scopolamine and tincture of stramonium in varying doses from time to time with some benefit. For the past three months she had been taking scopolamine $\frac{1}{400}$ grain three times a day.

Scopolamine was omitted and she was given 10 mg. of benzedrine sulfate twice a day. April 24 she returned feeling worse: "I feel all slowed up; my legs won't work so well." Her appetite also was poorer. However, she did not feel as drowsy as before. During the next two weeks she was given ephedrine sulfate three-eighths grain (0.024 Gm.) three times a day for the first week and three-fourths grain (0.05 Gm.) in the second. At the end of this period she felt a great deal worse in every way and presented all the classic symptoms of advanced Parkinson's disease, including frequent oculogyric crises. May 15 she was given scopolamine $\frac{1}{400}$ grain plus ephedrine three-fourths grain and in a week she returned feeling considerably better, but the eyes still bothered her. Omission of ephedrine had no effect one way or the other for four days following this.

May 28, 10 mg. of benzedrine sulfate twice a day was added to the scopolamine. The improvement in all the symptoms was then striking. She felt stronger, she had much more energy and a better appetite, there was much less rigidity, and tremor had disappeared. Oculogyric crises disappeared completely for three weeks. At this time, June 19, she ran out of benzedrine and was unable to get to the hospital for more for four days; she continued to take scopolamine, however. On the first day on which she took no benzedrine she had three oculogyric crises and her drowsiness, lack of energy, rigidity and anorexia returned. On resumption of the benzedrine with the scopolamine she was at once relieved and had remained so when last seen.

CASE 24.—J. B., an American schoolboy, aged 15 years, had encephalitis at the age of 3. About a year later his mother first noticed rigidity and tremor of the left arm and soon afterward of the left leg. This grew progressively worse and gradually there developed thickness of speech, some difficulty in swallowing, drowsiness, and lack of energy amounting at times to a marked apathy.

He was first seen April 14, 1936, at which time he was thin and malnourished, with a rigid, markedly tremulous and practically useless left arm, a rigid weak left leg which dragged when he walked, masklike facies with mouth hanging open and saliva running out of the corners, monotonous unintelligible speech, impaired postural reflexes, and increased deep tendon reflexes slightly more active on the left. Plantar responses were normal. He had received no treatment for several years.

He was given 10 mg. of benzedrine sulfate twice a day for one week without effect. Ephedrine three-eighths grain and later three-fourths grain three times a day was without apparent effect. May 5 he was given ephedrine three-fourths grain plus scopolamine $\frac{1}{400}$ grain three times a day. When seen May 12, definite improvement had been noted. Tremor and rigidity were diminished, he felt stronger and he could walk, talk and use his left arm better. Omission of ephedrine while he continued the scopolamine did not alter the improvement.

May 21, 5 mg. of benzedrine sulfate three times a day was added to the scopolamine and on his return, June 5, his mother said "He is a different boy; all the neighbors have noticed it. . . . he has so much pep and ambition and seems so cheerful. . . . he still shakes as much but he can use his arm better, and now he can run. . . . Every one can understand what he is saying now." Increasing the dose of benzedrine caused him to have "bad dreams" and lose his appetite, so he was maintained on the original dose and when last seen, July 1, he was getting along very well, in an improved condition.

THE STIMULATING ACTION OF BENZEDRINE SULFATE

A COMPARATIVE STUDY OF THE RESPONSES
OF NORMAL PERSONS AND OF
DEPRESSED PATIENTS

EUGENE DAVIDOFF, M.D.

AND

EDWARD C. REIFENSTEIN JR., M.D.

SYRACUSE, N. Y.

Benzedrine (beta-phenylisopropylamine) is a chemical compound related in structure and action to ephedrine and epinephrine. Barger and Dale¹ described this drug in 1910 as a member of a group of similar substances to which they gave the name sympathomimetic. The interest of investigators was centered on ephedrine until 1930, when benzedrine first received consideration.

At that time this compound was used in pharmacologic studies conducted on animals by Piness, Miller and Alles,² Hartung and Munch,³ Alles,⁴ Tainter⁵ and Alles and Prinzmetal.⁶ At first their attention was focused on the peripheral effects of the drug, but a marked action on the higher centers of the central nervous system was also noted. About the same time benzedrine was given prominence as an astringent to the human nasal mucosa, chiefly through the work of Bertolet,⁷ Byrne,⁸ Scarano⁹ and Wood.¹⁰ It was observed that overdosage, particularly in the latter part of the day, was prone to result in insomnia.⁶ Other physiologic actions were investigated by Myerson and Ritvo,¹¹ who reported on the relief of spasm of the gastro-intestinal tract by the use of this compound. A pressor action was noted, and this and other physiologic effects were studied by Myerson, Loman and Dameshek.¹²

The profound central stimulation noted in animals was found to be present in the human being by Prinzmetal and Bloomberg,¹³ who reported benzedrine much more effective than ephedrine in treating narcolepsy.

From the Syracuse Psychopathic Hospital and the Department of Psychiatry of the Syracuse University College of Medicine, Dr. Harry A. Steckel, director. A number of the patients were studied at the Manhattan State Hospital and a few at the Hospital for Joint Diseases, New York City.

This was confirmed by Ulrich, Trapp and Vigdoff¹⁴ and by Nathanson.¹⁵ Peoples and Guttman¹⁶ studied the pressor effect and reported concomitant alterations of mood in normal and psychotic individuals. Myerson¹⁷ recently investigated changes in mood and fatigue resulting from this compound in normal and neurotic persons.

Because of this central stimulating action, the possibility of employing this drug in the treatment of psychiatric cases naturally presented itself. One of us (E. D.) reported the result of benzedrine therapy on a series of self-absorbed and normal persons.¹⁸ Nathanson¹⁵ reported definite stimulation of the central nervous system in normal individuals. He also found the drug to have a favorable action in states of persistent exhaustion and ready fatigability. Further investigations of the effect of this compound on depressed psychotic and psychoneurotic patients were indicated and are incorporated in this communication.

METHOD OF INVESTIGATION

The sulfate salt of benzedrine was given to a number of individuals representing each of the following five groups: normal, self-absorbed organic, self-absorbed dementia praecox, depressed manic-depressive, and depressed psychoneurotic. After a period of careful physical and mental observation each of these individuals received daily for from ten days to two weeks an oral dose of benzedrine sulfate, usually from 10 to 30 mg., except in instances in which the drug was prematurely discontinued because of undesirable reactions. The effect of the medication was observed in mood, speech, motor responses and general efficiency. The structure of the psychosis (or neurosis), the total personality, the untoward manifestations and, whenever possible, the subjective sensations were also studied. None of the subjects except two of the normal group were acquainted with the nature of the medication.

EFFECT ON THE NORMAL GROUP

The effect of benzedrine was studied on ten normal individuals. Seven showed elevation of mood, seven overtalkativeness, and ten increase in both motor activity and general efficiency. In addition, five subjects exhibited a state of increased irritation. Three of the ten patients complained of fatigue during the administration of the drug, but several of the subjects who were fatigued prior to receiving it found that this symptom had disappeared. Two of the subjects suffered from lassitude after the medication was discontinued. Two others spontaneously requested more benzedrine after the period of administration was terminated. Other manifestations reported were flushing of the face; generalized feeling of warmth; sweating; greasiness of the skin; sensations of constriction, fullness or aching of the head; increase of the nasal secretion; injection of the conjunctivae; parching of the mouth and the throat; peculiar taste; anorexia; loss of weight; frequency of the bowel and the bladder function; constipation; abdominal cramps; throbbing pulse; consciousness of the heart action; tension of the muscles;

burning of the feet; insomnia; malaise and fatigue; dulness and forgetfulness; confusion, and inability to concentrate.

The following are illustrative cases:

CASE 1 (L. F.).—Blood pressure: before, 100/70; greatest variation after, 100/85. Three hours after the first medication the subject complained of heaviness of the head and a feeling of thirst. One hour later he became very active. He telephoned for flowers to be sent to a sick friend, but shortly after, becoming impatient, he hurried several miles to the florist shop and delivered the gift in person. He said "I wanted action, and I got it!" Later he complained of tension in his muscles and of fatigue. He slept well that night. The second day he noticed a general feeling of depression, increased frequency of urination and increased nasal secretion. The next day he perspired freely and his face became flushed; he was restless, "felt like reeling" and was mentally dull and retarded. On the fourth day he "felt terrible and groggy" and noted that his eyes were "red." On the next day he was "pepped up" and mentally alert. The following day he was annoyed by trivial errors in his work. Throughout the remainder of the period he continued to sleep poorly, made many of the same complaints and toward the end became forgetful.

CASE 2 (W. M.).—Blood pressure: before, 120/80; greatest variation after, 95/75. One hour after taking the medication the subject noticed perspiration and complained of a peculiar taste. Within six hours he noted increased activity and alertness. He called his superior officer on the telephone, insisted on taking an examination for which he was not eligible and became quite agitated during the discussion. He was embarrassed about the incident a few hours later. On the third day he noted exaggerated and prolonged physical and mental alertness. On the fourth day general sluggishness and malaise, clamminess of the skin, vague abdominal cramplike pains, and frequency of urination and defecation were present. On the seventh day he was depressed and complained of headache. After the eighth day he observed, in addition, greasy skin; pulse, at first rapid, then slower; increased physical and mental activity; feeling of warmth; loss of appetite, and decreased requirement of sleep. He noticed a burning sensation in his feet, a throbbing in the parietal region and a dull frontal headache. After the drug was discontinued he felt depressed and fatigued for several days.

CASE 4 (E. R.).—The medication was taken on several days when the subject was suffering from undue fatigue caused by lack of sleep. Within one hour there was a sense of warmth over the whole body and a feeling of well being, and the fatigue appeared to lessen or to disappear. There was a tendency to be overtalkative, a drive to do many things. He undertook many small accumulated tasks that were usually unpleasant and found pleasure in getting them accomplished. He was flowery in his speech, mildly euphoric, oversollicitous in his attitude toward others, and concerned with trifles. He reported that his mind was racing ahead of his physical accomplishment and he planned his program hours in advance, revising it as each hour passed. The feeling of warmth gave way to perspiration, and he noticed some restlessness and inability to sit quietly. There was frequency of urination, and the bowel movements were unusually copious and accompanied by mild abdominal cramps. There was at times a fullness in the head and a tendency to be irritable. At night there was some "let down" in the mood, but no definite fatigue. Sleep was moderately reduced, but the next morning he felt nothing out of the ordinary.

In addition, in other cases, the following observations were reported:

CASE 3 (J. O.).—On the first day the subject felt alert and happy and did not require much sleep. He said that he was more active and seemed stimulative. However, after the third day, except for slight exhilaration, the effects disappeared and he noticed nothing worthy of mention for the rest of the period.

CASE 5 (E. D.).—The first day the subject's sensations were those of jumpiness and irritability, a feeling of being on edge, and a tendency to hair trigger-like reactions and responses. He was impulsive and resentful of criticism. During a telephone conversation with his superior officer in which he was being reprimanded he abruptly hung up. Next day he was markedly overtalkative, facetious and joked about trivialities

that were usually unnoticed. On succeeding days these sensations diminished, and after the fifth day no reactions were noted.

CASE 6 (B. I.).—After medication on the first day the subject experienced a feeling of anxiety, felt his pulse throbbing and noted an inability to concentrate. He had a feeling of physical fitness and well being and was mentally stimulated and under tension. On the last day he felt tired.

CASE 7 (C. W.).—About one hour after medication the subject felt an urge to talk, which continued about two hours. The second day he felt sleepy for a short time, then became exhilarated and later irritable and “jumpy.” For the rest of the week he felt only slightly exhilarated, and no marked change was noted.

CASE 8 (P. R.).—After taking benzedrine the subject was forgetful, shaky, irritable, jittery, restless and tense. On the last day he had a feeling of mental and physical stimulation but complained that he could not relax.

Some of these effects on the normal person have been previously mentioned by one of us.¹⁵ Myerson¹⁷ reported that normal individuals suffering from mild fatigue with small doses of benzedrine experienced immediate relief of a pleasant sort and became calm. With 30 mg. several of the patients felt “jittery.” Nathanson¹⁵ stated that most normal individuals after a dose of from 20 to 30 mg. of benzedrine showed quite regularly one or more of the following effects: eupho-

ria, a feeling of exhilaration, lessening of fatigue, and increased energy and capacity for work and talkativeness.

EFFECT ON THE ORGANIC GROUP

The effect of benzedrine was studied on ten self-absorbed individuals in the organic group. Five evidenced elevation of mood, seven overtalkativeness, eight increase in motor activity and eight increase in general efficiency. In addition, three showed a state of increased irritation. There was no change in the total personality or the structure of the psychosis in any of the cases. The most consistent improvement was noted in the alcoholic and in the traumatic cases. In those patients in whom any effects were noted the subjective sensations appeared to follow the pattern of the normal group, but in addition confusion and unsteadiness of gait were observed. Several complained of fatigue during the administration of the drug. Of this group, eight cases studied by one of us at the Manhattan State Hospital have been reported in greater detail elsewhere.¹⁸

Of the cases showing improvement, the following is representative:

CASE 4 (J. W., alcoholic).—Blood pressure: before, 110/70; greatest variation after, 190/90. One hour after taking the drug the patient felt considerable motor and mental acceleration and stated that he felt “good.” There was a marked increase in talkativeness. His hands felt cold and clammy. At the end

of two hours he was confused and unsteady on his feet but insisted that he was feeling “very strong.” After three hours he was restless, talkative, whistled constantly, appeared very cheerful and for the first time since his admission he asked to go on the porch. He continued to be cheerful and to pace about for the rest of the day. He stated that he never felt better. He improved rapidly and was soon discharged from the hospital.

Of the cases that were adversely affected by the medication, the following are typical:

CASE 10 (R. L., parietic).—Blood pressure: before, 160/100; greatest variation after, 160/120. The patient showed no improvement but he became more depressed, less efficient and very sluggish and fatigued. The drug was discontinued prematurely because of the rise in the diastolic blood pressure.

CASE 9 (J. O., a cardiac patient).—Blood pressure: before, 170/120; greatest variation after, 110/65. The patient experienced a rapid fall in blood pressure, but was otherwise unaffected.

EFFECT ON THE DEMENTIA PRAECOX GROUP

The effect of benzedrine was studied on twenty-five self-absorbed dementia praecox patients. Four manifested elevation of mood, seven overtalkativeness, eleven increased motor activity and nine increased general efficiency. Five showed a state of increased irritation. Because of the mental state of the patients it was impossible to evaluate changes in fatigue properly. There was no change in the total personality or in the structure of the psychosis in any of the cases. Three, diagnosed as catatonic, were classified as improved and were paroled. Twenty-two of these cases, studied at the Manhattan State Hospital, have been reported in greater detail in a previous paper.¹⁸

The following cases are illustrative:

CASE 1 (J. G.).—Blood pressure: before, 100/60; greatest variation after, 130/100. The case was of the self-absorbed catatonic group of recent onset. Following the medication the patient began to initiate conversation and later discussed matters freely with the physician. He became a very efficient worker and was much more active. While his affect was still somewhat rigid, he showed an improvement in this phase. He smiled and at times indulged in humorous conversation.

CASE 13 (W. T.).—Blood pressure: before, 108/84; greatest variation after, 110/90. The patient seemed in no way affected throughout the entire period of administration.

Myerson¹⁷ referred briefly to eighteen patients suffering from dementia praecox who were treated for a considerable period with this drug. He concluded that benzedrine had no effect in catatonic states and none, as far as could be seen, in hebephrenia.

EFFECT ON THE MANIC DEPRESSIVE GROUP

The effect of benzedrine was studied on ten depressed manic depressive patients. Only two displayed elevation of mood, six overtalkativeness, six increased motor activity and six improved general efficiency. A state of increased irritation was observed in six. Several of the patients complained of fatigue during the administration. There was no change in the total personality or in the structure of the psychosis. The subjective statements were in no way strikingly different from those of the normal group.

Of the cases that improved the following is typical:

CASE 2 (N. W.).—Blood pressure: before, 106/62; greatest variation after, 120/80. The patient became talkative within an hour after taking the drug. Three hours later he was “feeling much better” but complained of fatigue. He did not sleep well. The second day he appeared depressed three hours after taking the drug, but from six to eight hours later he stated that he felt “good” and he slept well that night. On the fourth day he remarked that he was very happy, cheerful and alert.

The urinary output was diminished and the bowels were quite constipated. On the sixth day he was jovial. By the tenth day he was singing; he stated that he felt "great" and appeared to have reached approximately his normal state. He was quite active. On the twelfth day he was depressed shortly after taking the drug but toward evening appeared to be in better spirits. On the fourteenth day he was very talkative but complained of depression and a severe headache. Throughout the period he worked more efficiently in the ward. In general his mood appeared less affected than his speech response, motor activity and general efficiency.

The following is an example of the cases in which there was failure to improve:

CASE 8 (J. F.).—Blood pressure: before, 98/62; greatest variation after, 148/85. After taking 30 mg. of the drug the patient evinced no change. At a later date even though a massive dose of 70 mg. was administered, sufficient to raise the systolic blood pressure 50 points, there were no deviations in mood, speech, motor activity or general efficiency.

An alarming untoward effect was noted in one case:

CASE 9 (B. M.).—The patient became more irritated, more antagonistic, and more hopeless in his outlook. He sat at home and brooded. On the fifth night he attempted suicide by taking an overdose of barbiturate sedative and was in coma for some hours.

EFFECT ON THE PSYCHONEUROTIC GROUP

The summary in table 1 on the effects of benzedrine on ten depressed psychoneurotic patients reveals that

and became very talkative. The next day he complained of "drawing" sensations in the head and eyes and blurred vision. He experienced the same symptoms on the third and fourth days but became more cheerful. The amount and frequency of defecation and urination increased. The fifth day he appeared delirious for a time and complained of "water ebbing up and down his body to his neck." These sensations soon disappeared. The next day he could not remember anything that had happened and was confused. On the seventh day he was improved and became jovial and talkative, although the motor activity increased only slightly, and there appeared to be no change in his general efficiency. Toward the end he was occasionally drowsy. He complained of dizziness, even after the drug was discontinued.

Of the psychoneurotic cases that were unaffected the following is typical:

CASE 9 (H. C.).—Blood pressure: before, 140/85; greatest variation after, 152/98. After the medication there was no change in the patient's status, although she stated that she had "faith in the pills." The next day she was much discouraged because they had "failed to work." Her face was flushed; she ate poorly, felt fatigued and complained, as previously, about the bowels and stomach. The patient insisted that she would "never be able to get around again." Later she became very irritable and tearful at the slightest provocation. She complained of a "drawing" sensation in the head. On the third day she felt a little better than previously, but shortly declared: "the treatment is a fake just like everything else." She was then placed on placebo medication. Several hours later she was feeling much better but soon became depressed

not one of the cases showed improvement in all spheres. Only three showed elevation of mood, six increased talkativeness and four accelerated motor activity. The fact that only two cases showed improvement in general efficiency is interesting. Five of the cases showed a state of increased irritation. The total personality was unaffected in every case, and the underlying psychoneurotic tendency remained entirely unchanged. Many of the effects were recorded as slight, but one case showed a severe untoward reaction. The subjective statements of the patients followed the pattern of the normal group.

The following is an example of an improved case in this group, although there was a severe untoward reaction before the improvement became evident:

CASE 2 (F. H.).—Blood pressure: before, 108/60; greatest variation after, 138/90. One hour after taking the benzedrine the patient complained of feeling dizzy. Within four hours he became perturbed and agitated. He was unsteady on his feet and appeared to have a marked reaction, during which his eyes became glassy, his face was flushed, he perspired freely, knee jerks became hyperactive and he voluntarily went to bed. Motor activity was much diminished and he fell asleep for about an hour. Later his face was pale, and there was cyanosis of the lips and fingers. The next morning the initial pulse rate of 86 had decreased to 56. At the same time the systolic blood pressure was only 4 points above the original level. Within three hours he complained of fatigue, and the pulse went to 104, while the blood pressure was 126 systolic, 68 diastolic. He again experienced these reactions and voluntarily went to sleep. However, several hours later he felt much better

and discouraged again and asked if there was any one else in the hospital as sick as she. Her reactions on placebo medication were no different than they had been on benzedrine or, indeed, than they had been in the beginning. This case illustrates the difficulty in evaluating the effect of medication, particularly in the psychoneurotic group of patients.

Myerson¹⁷ reported that benzedrine sulfate acted as an ameliorative influence in certain cases of neurosis associated with depression, fatigue and anhedonia. He pointed out that it was not in any sense curative, and its effects were not permanent, but stated that it helped to dissipate the morning apathy and depression. Nathanson¹⁵ asserted that the drug acted favorably in persons with a persistent tired feeling and a ready fatigability, whom he included under the diagnosis of "nervous exhaustion."

COMPARISON OF THE NORMAL AND THE ABNORMAL GROUPS

Table 2, containing a summary of the reactions of the various groups to benzedrine sulfate medication, indicates that the normal group had the largest percentage of response in every sphere. The organic group was next and surpassed every other division of the abnormal groups in each of the reaction phases. The scattering of the reactions, the lack of consistency and the indifferent response in efficiency in the psychoneurotic group is also worthy of comment. The table shows that elevation of the mood was the least marked reaction in every one of the groups, including the normal.

COMMENT

It is difficult to state whether the manifestations observed following the administration of benzedrine sulfate were due to the action of the drug itself, to the variable course of the mental illness in question or to the psychotherapeutic effort entailed in the procedure. As far as possible, consideration must be given this source of error in the interpretation of the results. More extensive investigation is necessary before final conclusions can be reached.

A discussion of the effects noted follows:

1. *Mood*.—Of all the reactions tabulated, elevation of mood was the least frequent occurrence as far as the abnormal cases were concerned. This alteration occurred in fourteen of these cases, or 25.5 per cent. It is interesting to note, however, that 70 per cent of the normal group showed this reaction. In interpreting these responses it must be emphasized that increased motor or increased speech activity does not necessarily imply elevation of the mood. The only other significant variation of the mood was a state of disgruntled irritation, which appeared in twenty-four of the cases, including five of the normal group. Depression was produced or aggravated in some individuals, particularly those who complained of excessive fatigue. Elevation of mood occurred, in general, most frequently in the normal and in the organic groups.

2. *Talkativeness*.—This reaction was present more frequently than elevation of mood but less often than increased motor activity in the abnormal groups. Loquaciousness was observed in at least 60 per cent of the abnormal cases, with the exception of the dementia praecox group, in which only 28 per cent were affected. Seventy per cent of the normal group manifested increased speech activity. None of the patients evinced a decreased desire to talk.

3. *Motor Activity*.—Hyperactivity was the most frequent reaction noted in the abnormal cases. All of the normal group and 80 per cent of the organic cases showed increased motor activity, while the dementia praecox and the psychoneurotic groups were considerably less affected. Decreased motor activity was observed in some, particularly in those who complained of fatigue and who were more depressed, drowsy and sleepy.

4. *General Efficiency*.—As far as the abnormal groups were concerned improvement in general efficiency approximated increased talkativeness in frequency of occurrence. The normal and the organic cases again presented the most constant response. All the normal cases and 80 per cent of the organic improved. The lack of improvement in the psychoneurotic group is in striking contrast to the normal.

5. *Comparison of Groups*.—In general, the most marked response in all the various phases studied was found in the normal group. The organic cases, particularly the alcoholic and the post-traumatic, closely paralleled the normal.

6. *Structure of Psychosis (or Neurosis) and Total Personality*.—None of the abnormal cases showed any noteworthy alteration in the structure of the psychosis; nor was the central neurotic tendency or the total personality reaction modified by the benzedrine therapy.

7. *Fatigue*.—Many of the patients who responded to the drug noticed amelioration of fatigue, and this was particularly true of those who were feeling tired prior to the administration of the benzedrine. Myerson¹⁷

and Nathanson¹⁸ report similar responses in fatigued individuals. A number of our patients, however, who did not have this complaint prior to medication noticed sensations of fatigue from three to six hours after taking the drug. Another group showed, for one or two days, a fatigue on awakening that appeared rather consistently about four or five days after the benzedrine was started. After the medication had been entirely discontinued, several of the patients complained for a day or two of lassitude. It must be borne in mind, therefore, that benzedrine, instead of relieving the malaise for which it is prescribed, occasionally may induce additional fatigue.

8. *Other Central Effects*.—In addition to the alterations in mood, speech and motor activity, general efficiency and states of fatigue mentioned before, benzedrine sulfate also produced other effects on the central nervous system. Among these should be included insomnia and decrease of sleep requirement, alertness, increase in accessibility, increase in subjective verbalization and willingness to discuss personal problems, increase in meticulousness, resentfulness, impulsiveness, impatience, anxiety, surliness, increase in self assertiveness approaching aggressiveness in some, facetiousness, increase in spontaneity, agitation, drowsiness, inability to concentrate, dulness, forgetfulness, confusion and transitory delirium, tactile hallucinations, malaise, dizziness and an increase in drive or urge. A very commonly occurring manifestation was an irritable restlessness, which was often annoying.

9. *Peripheral Effects*.—Most of the cases showed some peripheral effects. Among them should be mentioned flushing of the face, urticaria and pustular eruption of the skin, generalized sensation of warmth, sweating, coldness and clamminess of the hands, greasiness of the skin, sensations of constriction, fullness or aching of the head, increase or decrease of the nasal secretion, injection of the conjunctivae, dilatation of the pupil, parching of the mouth and throat, peculiar taste, anorexia, nausea, loss of weight, abdominal cramps, frequency of bowel and bladder function, constipation, decrease in urinary output, throbbing pulse, consciousness of heart action, tension of the muscles and generalized tremulousness, burning of the feet, and other vasomotor effects such as dermatographia, pallor and cyanosis.

10. *Physiologic Reactions*.—Physiologic reactions in some of the cases have been carefully studied and will be reported in detail in another paper. The results were variable, uncertain, unpredictable, and at times paradoxical. As Rothlin¹⁹ has pointed out, this might be explained by the fact that disturbances in the vegetative nervous system almost invariably involve parasympathetic as well as sympathetic stimulation. The observations on the physiologic action of benzedrine sulfate are summarized briefly as follows:

A. Skin, Mucous Membrane and Vasomotor System: most of the reactions mentioned under the peripheral effects.

B. Bowel and Bladder Function: increase in frequency of bowel action; increase in amount of stool; constipation; abdominal cramps; increase in frequency of bladder action; increase or decrease in daily urinary output.

C. Body Weight: decrease in most subjects.

D. Blood Pressure and Pulse: increase or decrease in systolic and diastolic blood pressure levels; increase or decrease in pulse rate.

E. Respiration: apparently unaffected.

19. Rothlin, cited by Jores, A., and Goyert, C.: The Treatment of Vegetative Excitation, *Clin. Med. & Surg.* 42: 498, 1936.

F. Temperature: slight increase or decrease.

G. Basal Metabolic Rate: increase or decrease, no consistent variation.

H. Blood Sugar and Nonprotein Nitrogen: apparently unaffected.

I. Knee Jerks: occasional increase.

J. Cellular Elements of the Blood: no striking variation, except for a moderate increase in one case.

Our observations to date seem to be in accord with the statement of Sollmann²⁰ on the variable effects of the other sympathomimetic drugs on urinary output. We have not found that the alterations in the blood pressure can be used as an index of the course and intensity of intoxication with benzedrine, as mentioned by Peoples and Guttman.¹⁶ The striking erythrocytosis and leukocytosis noted in some cases by Myerson and his associates¹² have not been observed, although one case showed a moderate increase. As far as the intensity of all reactions could be evaluated, the asthenic individuals appeared to be more sensitive to benzedrine than the pyknic types.

11. *Untoward Effects.*—A number of the reactions to benzedrine must be classified as untoward, either because they involved unpleasant subjective sensations or else because they rendered the patient objectively less adaptable. Such reactions were observed in the central, peripheral and physiologic spheres and have been mentioned before under those headings. Subjectively, the following central effects were particularly annoying: a feeling of undue fatigue or malaise, insomnia, dizziness, increase in depression and hopelessness, a feeling of anxiety and a disturbing sensation of restlessness or tension. Some of the patients could not define their feelings satisfactorily yet feared the drug because of the uncomfortable sensations and even refused to continue taking it. Objectively, impulsiveness, aggressiveness, and assaultiveness, inability to concentrate, dulness and forgetfulness, confusion and transitory delirium proved therapeutic obstacles. This was especially true when several of these manifestations occurred in combination, as in the frequent appearance of a state of irritated restlessness. In a few cases of dementia praecox, usually with a history of previous catatonic excitement, the occurrence of overactivity, impulsiveness, surliness and boisterousness made the patients more difficult to manage. One of the manic depressive patients became more depressed and impulsively attempted suicide. In a psychoneurotic patient transitory delirium developed with hallucinations. A dementia praecox patient made a homicidal attempt on his wife shortly after the termination of the benzedrine medication, but the causal relationship is not definitely established.

Patients also expressed annoyance at some of the peripheral effects, which have been listed in detail under that heading. However, except for tremulousness, none of them interfered to any degree with the management of the patients. There were a number of untoward occurrences associated with the physiologic reactions. The vexation of patients at changes in the skin, mucous membranes, vasomotor system and bowel function has already been mentioned. The loss of weight was a source of concern to a few. Objectively the appearance of an excessive elevation or a paradoxical fall in the blood pressure or in the pulse rate was viewed with considerable apprehension, particularly when vasomotor phenomena were present and in several instances neces-

sitated the discontinuance of the benzedrine. One of the psychoneurotic patients had recurring episodes of vasomotor and emotional instability, which were severe and at first rather alarming. Another patient with marked vasomotor instability exhibited a rise of the systolic blood pressure of over 100 points following the ingestion of 20 mg. of benzedrine sulfate.

The action of benzedrine can usually be terminated by appropriate doses of barbiturates. The use of ergotamine tartrate, recently shown to be generally antagonistic to epinephrine,²¹ should be borne in mind, and this drug should be investigated as a possible antagonist to benzedrine sulfate.

Untoward reactions have been reported by other investigators. Prinzmetal and Bloomberg¹³ noted insomnia in several of the cases of narcolepsy but found this easily corrected by adjusting the dosage. They also reported patients becoming irritable and irascible when the dosage was carried too high. Myerson¹⁷ mentioned two cases in which the drug had to be discontinued because of the appearance of noisy, threatening and uncontrollable behavior. Nathanson¹⁵ had to discontinue the drug in three patients, two because of insomnia and one because of severe palpitation.

In view of these untoward and disturbing reactions, it must be pointed out that benzedrine sulfate can be more safely prescribed when the patient is under close observation in a hospital. Its use in outpatient practice should be undertaken with considerable caution and only under favorable circumstances.

12. *Habit Formation.*—Most of the patients affected by the drug who experienced few or none of the untoward effects seemed to enjoy the sensations produced, and several requested more medication when the period of study was ended. One compared the sensation to that of a mild state of alcoholic intoxication, and those who had a liking for spirituous liquors particularly relished the drug. Without further study the question of habit formation cannot be satisfactorily answered, but it would seem that there is sufficient evidence to warn against promiscuous use. As none of the patients mentioned in the present report received the drug for more than a few weeks, no observations could be made on the possibility of addiction, development of tolerance or late untoward effects from prolonged use. In this connection, however, Prinzmetal and Bloomberg¹³ have given the medication daily for fourteen months, Myerson¹⁷ for six months and Nathanson¹⁵ for four months without incident. The last named suggested a possible harmful effect in prolonged administration from the excessive expenditure of energy beyond the capacity of some individuals.

13. *Dosage.*—In view of the disturbing nature of some of the untoward reactions, it is always advisable to start administering benzedrine in small doses, as Prinzmetal and Bloomberg¹³ have suggested. This will also aid in detecting any idiosyncrasy. Most of our patients received from 10 to 30 mg. of the drug daily. Some of the unresponsive patients appeared equally unaffected with doses of from 20 to 70 mg. Prinzmetal and Bloomberg¹³ gave narcoleptic patients as much as 105 mg. daily with only moderately unpleasant reactions. One patient in our series received 200 mg. in one day without exhibiting a much greater reaction than could be obtained with 20 mg. The reactions appeared from one to three hours after the administra-

20. Sollmann, Torald: *A Manual of Pharmacology*, Philadelphia, W. B. Saunders Company, 1936, pp. 405-432.

21. Baber, E. A., and Tietz, Esther B.: The Effect of Ergotamine Tartrate on the Behavior of Psychotic Patients, *J. Med.* 17: 551 (Jan.) 1937.

tion of the drug and persisted from three to eight or nine hours. It was found possible in one patient to maintain the reaction at its height for twelve hours by repeating 20 mg. of benzedrine every two hours. Our observations gave insufficient data to warrant a discussion of the problems of optimal dosage, cumulative effect and increased tolerance; however, many of our patients experienced a maximal effect within one week.

14. *Contraindications.*—It is agreed by all investigators that the presence of the following are definite contraindications to the administration of benzedrine sulfate: (a) hypertension, (b) coronary artery disease and (c) a state of manic excitement. It has been our observation that this drug should not be used in most forms of cardiac and vascular disease.

In addition to these definite contraindications there are a number of circumstances under which benzedrine should be administered with considerable caution, because of possible harmful effects. We include among these (a) idiosyncrasy to small doses of the drug, or the early appearance of alarming untoward effects; (b) more severe forms of vasomotor instability, (c) wide daily fluctuations in the blood pressure or in the pulse rate, (d) tendency to physical overactivity, as observed in the agitated depressions; (e) history of previous excitement, as in catatonic dementia praecox, epilepsy and mental deficiency; (f) history of homicidal or suicidal tendencies; (g) history of convulsive seizures; (h) anorexia; (i) insomnia, and (j) malnutrition and states of exhaustion, debility and lowered bodily resistance. The apparent increased sensitivity of asthenic individuals should be considered. In severe depressions the possibility of suicide must always be kept in mind. Habituation to the drug cannot as yet be entirely dismissed.

15. *Indications.* — Benzedrine has been widely accepted as a local astringent.²² As an internal medication it has been best established in the treatment of narcolepsy.²³ It has also been suggested in overcoming persistent states of fatigue and "nervous exhaustion";²⁴ in postencephalitic parkinsonism;²⁵ in conditions in which it is desirable to produce an elevation of the blood pressure;¹² in relieving gastro-intestinal spasm;¹¹ in combating overdoses of barbiturates;¹² in preparing individuals for periods of excessive physical or mental exertion;¹⁵ as an adjuvant to the action of atropine, stramonium and scopolamine²⁶ and in relieving attacks of migraine.¹⁵ These suggestions need further substantiation.

SUMMARY

As we have previously mentioned, more extensive investigation of the action of benzedrine sulfate is necessary before final conclusions can be reached. However, our experience, limited as it has been to the sixty-five cases presented in this communication, prompts us to suggest the following:

A. Benzedrine sulfate is apparently more stimulating to normal persons than to depressed or self-absorbed patients.

B. It is more effective in increasing the motor activity, the speech activity and the general efficiency than in elevating the mood.

C. It is of more value in the organic depressions, particularly the alcoholic, than in those of psychogenic origin.

D. It may be of value in differentiating the states of depression due to alcohol alone, which are usually rapidly dissipated by the drug, from the states of alcoholic depression superimposed on and masking depressions of psychogenic origin, which do not respond readily to the drug.

E. It may render depressed or self-absorbed patients more accessible to investigation or psychotherapy.

F. It may be of use in reducing weight.

G. The beneficial effects of benzedrine sulfate therapy may be counterbalanced by untoward reactions occurring in the course of the administration. This drug should be employed with caution and under favorable circumstances.

H. Are there any benefits to be gained from prolonged administration of benzedrine sulfate that cannot be obtained from a brief exhibition with adequate dosage?

I. Benzedrine sulfate apparently may accelerate the rate of improvement in cases in which ultimate recovery is likely to be the inevitable result.

ADENOCARCINOMA OF THE RECTUM WITH UNUSUAL SITES OF METASTASES

REPORT OF TWO CASES

JUSTIN J. STEIN, M.D.

AND

FERDINAND K. HANTSCH, M.D.

HINES, ILL.

Adenocarcinoma of the rectum seldom metastasizes or invades the penis by direct extension. A careful review of the literature has revealed only two similar cases. In 1933 Niewiesch¹ reported a case of adenocarcinoma of the rectum in a man aged 69. One and one-half years following resection of the rectum he returned because of priapism. No recurrence was found in the resected area, but the corpora cavernosa were rigid as the result of invasion by tumor tissue. Amputation of the penis was done, but the patient died ten months later from metastases.

Matheson² in 1935 reported a case of adenocarcinoma of the rectum in a man, aged 72, with secondary carcinomatous deposits in the penis. The lesions were nodular and located on the dorsal surface of the penis. One month after his admission the deposits compressed the urethra, causing complete repression of urine. Necropsy and sections reviewed for histologic study confirmed the diagnosis of an adenocarcinoma of the penis having the same histologic structure as the rectal lesion. Priapism was not mentioned.

The case to be reported (case 1) is the sixteenth recorded in the literature of secondary involvement of

the penis by carcinomatous tissue. Frontz and Alyea,³ Cowie,⁴ Paglieri and Schiappapietra,⁵ Guibal⁶ and Martin-Laval⁷ reported cases with the prostate as the primary site; Kessell,⁸ Neumann⁴ and Paschkis⁹ the bladder; Bergeret⁴ and Garofalo¹⁰ the testicle; Gadrat¹¹ the liver and Begg¹² and Reinecke⁴ the kidney. As previously mentioned, in the cases reported by Niewiesch¹ and Matheson² the rectum was the primary site. Four of the cases reviewed by Niewiesch¹ gave a very definite history of priapism. Priapism was present in the cases reported by Kessell⁸ and Niewiesch.¹

When priapism is seen, it is well to keep in mind the possibility of its being caused by metastasis or that it is the result of invasion from tumors situated in neighboring structures. The priapism may be present before one has evidence of the location of the primary lesion.

Fig. 1 (case 1).—Section of biopsy from rectum showing typical adenocarcinomatous structure.

The priapism is not caused entirely by the replacement of the corpus cavernosum by tumor tissue but also by the stasis and thrombosis of the sinuses in the corpus cavernosum not directly involved in the tumor process. There is no mention in the literature of a case in which secondary carcinomatous involvement of the corpus spongiosum urethrae has occurred.

It is remarkable that metastases or direct extension of tumor cells does not occur more often to the penis

from the rectal region because of the close proximity to that structure. The region between the rectum and the penis is devoid of all lymphatics that may drain the rectum anteriorly to the penis, as far as is known at the present time. Anatomically or physiologically,

Fig. 2 (case 1).—Section of biopsy from the penis showing identical structure as rectal lesion.

metastases from the rectum to the penis cannot be explained on a vascular or lymphatic basis. The only logical explanation is that the secondary involvement resulted from direct extension into the corpus cavernosum by way of the ischiorectal fossa and then through the junction of the deep and superficial triangular

Fig. 3 (case 1).—Lesion in rectum as seen from within the rectum. Almost complete obstruction has taken place.

ligaments with the fascia of Colles into the superficial perineal space. This is the course of least resistance, and the cells do not spread against fascial planes. It is considered unlikely that it passed through the urogenital diaphragm, for in this region such extension would be against fascial planes. The fascia of the urogenital diaphragm is thin, however; and could be involved. In

the event that the corpus spongiosum is involved, the extension would probably have to take place through the urogenital diaphragm.

REPORT OF CASES

CASE 1.—History.—A white man, aged 62, a farmer, was admitted to the Edward Hines Jr. Hospital, Jan. 29, 1936, stating that about fourteen months previous to admission he began to have frequent attacks of diarrhea consisting largely of blood and mucus. Shortly after the onset of the diarrhea he was examined by a private physician and was told that the rectum was essentially normal. Shortly afterward he began

Fig. 4 (case 1).—Several small nodules can be seen on the glans penis. Healed area on the dorsum represents the site from which biopsy was taken.

to have cramping pains in the perineal region. The stools had decreased in size until they were about the breadth of a pencil. Two months before his admission he first noticed several small hard nodules that appeared along the shaft of the penis. Since that time new nodules had appeared and the original nodules had increased in size. At times he had a dull aching type of pain associated with the penile lesions. During the past year he had lost 40 pounds (18 Kg.) and had become quite weak.

The patient had had the usual childhood diseases and no operations. His general health had always been good until the onset of the present illness. He fell and injured his back in 1926 but he had fully recovered from this at the time of examination.

The family history was irrelevant. There was no history of cancer, diabetes, tuberculosis or cardiac disease.

The patient had always been a farmer. He used alcohol and tobacco in moderation. He stated that he had had neither syphilis nor gonorrhea.

Physical Examination.—The patient was poorly nourished but fairly well developed. He was lying in bed and appeared markedly anemic and in a weakened state. The eyes, ears and nose were normal. The teeth were in fairly good condition. The tongue was coated. The tonsils and pharynx were normal. There were no abnormal pulsations in the neck and there was no cervical adenopathy. The thyroid gland was not remarkable. The trachea was in the midline. The heart and lungs were normal on clinical examination. The blood pressure was 100 systolic, 70 diastolic; the pulse 90; the temperature 98.6 F. There were no palpable masses, fluid, rigidity or tenderness in the abdomen and no scars. The spleen and liver were not palpable. No evidence of hernia was noted. There was no supraclavicular, infraclavicular, axillary, epitrochlear or inguinal adenopathy. The extremities were normal. Proctoscopic examination revealed an intrarectal mass starting at a point 6 cm. above the anus and extending to a distance 11 cm. above the anus. The mass circumscribed the bowel and was ulcerated in areas, especially the left half. The mass was firmly fixed anteriorly. There were several hard nodules located along the shaft of the penis and on the glans penis. The nodules varied in size from about 1 cm. to 2 cm. in diameter.

X-ray examination of the chest revealed an old inflammatory process, most probably the result of tuberculosis (inactive). Urinalysis was negative. The Wassermann and Kahn reactions were negative. Red blood cells numbered 3,560,000, leukocytes 11,600 with 86 per cent polymorphonuclears, and hemoglobin was 55 per cent. Fluoroscopy with a barium sulfate enema

revealed a large filling defect in the region of the rectal ampulla extending for a distance of about 10 cm. to the rectosigmoid region. Roentgenograms of the bones of the dorsolumbar spines, hips and sacro-iliac joints revealed evidence of an inflammatory process involving these structures. Calcification was present in the abdominal aorta.

The diagnosis of a biopsy specimen removed from the rectum was adenocarcinoma. Tissue removed from a nodule in the corpus cavernosum revealed an adenocarcinoma arising from the rectal mucosa.

Course in Hospital.—It was considered advisable for the patient to have a colostomy because of the very narrow lumen. The patient, however, refused. He was given a course of high voltage roentgen therapy resulting in practically no change in his condition. During the last few days of his illness the patient complained of priapism caused by the nodules of tumor tissue in the corpora cavernosa. He died April 16. All efforts to obtain a necropsy were futile.

There is no record of any case in the literature presenting metastasis to the bones of the foot from a rectal carcinoma. In case 2 the tumor in the foot appeared several months before there was any demonstrable evidence, clinical or laboratory, of involvement in other parts of the body. The metastasis is most likely to have taken place through the blood stream. Martin,¹³ Buie,¹³ Broders¹³ and Kernohan¹³ have never encountered a case similar to either of the ones reported in this paper.

CASE 2.—History.—A white man, aged 38, a laborer, was admitted to the Edward Hines Jr. Hospital May 1, 1935.

The father had died of heart disease. The mother, three brothers and three sisters were living and well. There was no history of tuberculosis, cancer, diabetes or insanity in the family.

The patient had had the usual childhood diseases. He stated that he had had no venereal diseases. There was no history of alcoholism or drug addiction.

The patient stated that he had experienced difficulty in keeping the bowels regulated for the past ten or twelve years. Two

Fig. 5 (case 2).—Appearance of foot representing the metastasis to bones of the foot from the rectal lesion.

years previous to admission he consulted a physician, who made a diagnosis of carcinoma of the rectum following examination with roentgenograms. Operation was advised but refused. At that time a partial obstruction was present and the stools were pencil-like in character and contained blood on several occasions. One year after the diagnosis of carcinoma of the rectum was made the patient was admitted to the Mercy Hospital. A proctoscopic examination of the rectum revealed a constricting ulcerated mass 10 cm. above the anus. Following biopsy a

13. Personal communication to the authors.

diagnosis of adenocarcinoma of the rectum was made. Roentgenograms of the pelvis and chest were negative. There was a swelling of the dorsum of the right foot first noted in February 1935.

Roentgenograms of the right foot revealed a destructive process in the head of the second metatarsal and second cuneiform with beginning obliteration of the cuneometatarsal joint and fusion of the navicular, cuboid and third cuneiform.

The patient was operated on by Dr. Lester E. Garrison at the Mercy Hospital, March 2, 1935. An inoperable carcinoma of the rectum involving the pelvic wall and glands along the iliacs

Fig. 6 (case 2).—Section of biopsy from bones of foot revealing a typical adenocarcinoma which is identical with the biopsy from the rectal lesion.

and aorta was found. A colostomy was performed. The right foot was explored and all degenerated bone tissue curetted. Pathologic diagnosis was metastatic papillary adenocarcinoma of the right foot with the primary lesion probably in the intestine. Roentgenograms of the pelvis including the upper third of both femurs made April 30 revealed an area of rarefaction involving the neck of the right femur.

A course of high voltage roentgen therapy was given by Dr. Henry Schmitz. Sixteen treatments were given through two portals over the rectal area and five treatments to the right foot. This was done as a palliative measure. Factors of treatment were as follows: 800 kilovolts, 10 milliamperes, 5 mm. of copper filter and 250 roentgen units each treatment. Following the completion of the roentgen therapy the patient was transferred from the Mercy Hospital to Edward Hines Jr. Hospital, May 1.

Examination.—On admission the patient appeared emaciated and chronically ill. The right leg and foot were in a plaster cast. Examination of the eyes, ears, nose and throat gave negative results. There was no adenopathy in the neck. The blood pressure was 132 systolic, 76 diastolic. The heart rate was 120. There were no murmurs. The lungs were normal. There were no palpable masses in the abdomen or nodes in the groin. The scar of the previous operation had healed. The colostomy was in good condition. Examination through a window in the cast revealed two cavities about 1.5 cm. in diameter extending downward for a depth of 2 cm. on the dorsum of the right foot. Considerable swelling and purulent drainage were present.

Urinalysis was negative. The Wassermann and Kahn reactions were negative. The blood count revealed: red blood corpuscles 4,200,000, leukocytes 7,200, hemoglobin 80 per cent. Roentgenograms of the right femur confirmed the condition as given at Mercy Hospital. Rectal changes were similar to those reported at Mercy Hospital. Roentgenograms of the chest, pelvis and lower lumbar vertebrae revealed no evidence of metastasis.

Biopsy of the right foot revealed an adenocarcinoma, metastatic in origin.

Course in Hospital.—The patient became progressively worse. Shortly before his death, nodules could be palpated in the liver. Also fluid appeared in the abdomen. He died July 6.

Necropsy revealed adenocarcinoma of the rectum with extension to the pelvis and metastases to the lungs, pleura, liver, lymph nodes, right leg and right foot.

THE RADIOACTIVITY OF THORIUM DIOXIDE SOL

A PRELIMINARY REPORT

ROBERT B. TAFT, M.D.

CHARLESTON, S. C.

The use of stabilized thorium dioxide sol (thorotrast) for roentgen visualization of the liver and spleen has become a well established clinical procedure, but the question of its radioactivity and the resultant effect on the reticulo-endothelial system is far from settled. The manufacturer places a warning in each box stating that the matter should be seriously considered.

Many observers have asserted that the radioactivity of this preparation is negligible as it causes no fogging of a film in many hours' time, but this is far too crude a method of detecting small quantities of radiation.

The Geiger counter,¹ when brought in the vicinity of a sample of thorium dioxide sol, showed such violent and immediate response that I at once realized that I had a means of making observations of comparatively high accuracy. Though the instrument described is capable of making only gamma ray tests, it is substantial and rugged as well as free from disturbances of moisture.

These experiments may be divided into the following steps:

1. Comparison of the gamma ray output of a clinical dose of thorium dioxide sol with a suitable radium standard.
2. The determination of the radioactivity of a phantom liver containing the entire clinical dose of thorium dioxide sol, to establish a basis from which to make percentage comparisons.
3. Tests made on the living patient who has been injected with thorium dioxide sol.

Fig. 1.—The Geiger counter is used to determine the radioactivity of one clinical dose of thorium dioxide sol by placing the three ampules an arbitrary distance from the Locher tube and recording the number of impulses over a long period of time. The "jig" is used to fix the exact distance each time.

4. Tests on the liver of a patient, removed after death.
5. Tests on the ash of liver.

1. The Geiger counter is set up and, with all possible source of radioactive material removed from the vicinity, counts are made over long periods of time to establish the number of impulses per minute which are being

1. Taft, R. B.: Technical Data Concerning the Geiger Counter, *Radiology* 26:756-757 (June) 1936.

recorded from the cosmic radiation and any other sources. This is subsequently referred to as "base rate." A sample of radium salt containing 3 micrograms of radium element is placed about 8 inches from the counter (fig. 2) and again counts are taken over long periods of time (thirty minutes or more) to establish the number of impulses per minute. This number

Fig. 2.—A tube containing a small amount of radium salt is substituted for the thorium dioxide sol and the impulses again are recorded.

is corrected for error by subtracting the "base rate" from it. The radium sample is then removed and the three ampules of thorium dioxide sol (a total of 75 cc.) are placed in exactly the location formerly occupied by the radium (fig. 1) and the rate per minute is again counted. These two figures when corrected for base rate error will be in the same proportion as the radioactivity of the specimens. A typical test:

Average counts from 3 micrograms of radium 56.7
Average counts from clinical dose of thorium dioxide sol (total of 75 cc.) 25.7
 $56.7 : 25.7 = 3 : x$

Where x is equivalent amount of gamma ray from thorium dioxide sol,
 $x = 1.36$ micrograms of radium

These counts are, of course, repeated many times with different distances and with filtration as great as three-eighths inch (0.32 cm.) of lead, which would show that only gamma rays are entering the chamber.

2. The "phantom liver" is prepared from wax and molded on an average normal liver. After the wax has

Fig. 3.—The phantom liver is used as a basis for making percentage calculations of the radioactivity of the human liver in the living patient.

hardened it is cut in two, the liver is removed and the halves of the mold are sealed together, leaving a hollow cast the interior of which is the same size and shape as the original liver. A small hole is drilled in the cast and it is filled with a mixture of water and one clinical dose of thorium dioxide sol (75 cc.). This is to serve as a standard of radioactivity from which to make percentage calculations when tests are run on the liver of a

living patient. The wall of the phantom is made as nearly as possible the thickness of the human flesh covering the liver. With the counting chamber fastened against the phantom (fig. 3) counts are made over long periods of time. The average number of impulses was found to be 52.8 per minute.

3. Several days after the patient had received the clinical dose of thorium dioxide sol (75 cc.) and roentgen examination showed good delineation of the liver and spleen, tests were made by placing the counting chamber on the body at the point estimated to be the nearest to the liver (fig. 4). Counts on different dates showed that the amount of thorium in the spleen was increasing. The counts were then compared to those on the phantom. Averages were as follows:

CASE 1.—Injections were given March 24, 27, 28, 1936.

Average counts March 29, 7.1, or 13.5% of total dose in liver.

Average counts April 2, 9.1, or 17.3% of total dose in liver.

Average counts April 28, 12.3, or 23.3% of total dose in liver.

Death occurred May 4.

Another patient, still living, showed activity of 32.4 per cent in the liver thirty-seven days after injection. It is of interest that a fairly high count was obtained over the spleen and small though definite counts were obtained over the skeleton, but no attempt was made to calculate these.

Fig. 4.—The tube is placed against the liver of the patient and the percentage of the total dose in the liver is determined by comparison with counts on the phantom.

It is to be noted that these figures are somewhat in disagreement with the final tests on the liver at autopsy and, as they cannot be repeated on the same patient, it will not be until after this presentation that the sources of error can be determined, as a number of cases will have to be worked out.

4. The liver was removed after death and, as the body had already been embalmed, the embalming fluid was tested for radioactivity and found nonactive. The counting chamber was placed near the liver but spaced with a rubber bag (fig. 5) partly filled with water in an effort to get the same spacing as the human flesh would give. The average of the counts on the liver was 24.5 per minute. This number, when compared with the numbers obtained from the phantom, showed that the liver contained 46.5 per cent of the total clinical dose of thorium dioxide sol (75 cc.).

5. As another check on the total amount of radioactive material in the liver, it was reduced to ash in order that it might be put in a small container. After the liver was chopped in small pieces it was run through a meat grinder and placed in a large evaporating dish. This was placed on a bath of boiling water for twenty-four hours to remove most of the moisture and for-

maldehyde. The material was then burned for several hours at a temperature of 450 C. The resulting ash was a powder that could be placed in a large test tube. This material was then compared with the three ampules of thorium dioxide sol and was found to contain 51 per cent of the original dose. It is seen that this compares very favorably with the result of method 4.

Fig. 5.—The liver removed at autopsy, after being hardened, is subjected to counting with the water bottle acting as spacing equivalent to the flesh. Afterward the liver is burned to ash and the radioactivity determined as in figure 1.

Conclusions drawn from these tests show that a clinical dose of thorium dioxide sol (75 cc.) gives the gamma ray activity equivalent to approximately 1.37 micrograms of radium and that little of this is excreted, the greatest part being stored in the liver and spleen, with some in the skeleton. Considering the effects of radioactive substances in the body, we naturally turn to the literature of accidental poisonings in industry which was so thoroughly written by many workers, particularly Dr. H. S. Martland. The argument can be justly advanced that in all these cases the amount of material was much greater than the amounts used for diagnostic purposes, but in most instances they were ingested and a high percentage excreted, whereas those injected intravenously are practically all retained. Martland² states that:

Biologically, the alpha rays are more destructive than either beta or gamma rays, the relations being 10,000 to 100 to 1. Therefore, radioactive elements in such small quantities that the beta and gamma radiations are almost negligible still produce, through their alpha radiations, intense physiologic effects, if given by mouth or vein.

In addition, the preponderance of mesothorium in luminous paint is of great toxicologic importance since the mesothorium in equilibrium with its radiothorium emits five alpha particles, whereas radium emits only four; also, the alpha particles of mesothorium and the products of its decay have greater velocity and penetration than those of radium, and, therefore, are, chemophysically and physiologically, more active.

The smallest amount of material determined in a complete autopsy was 14 micrograms,³ and that from the body of a physicist who died of radium poisoning. Attention is called to the fact that, in living patients suffering from severe radium poisoning, as little as 2 micrograms has been found to be present in the entire body,² which is not much above the amount noted in my experiments. My opinion is that the injection of thorium dioxide sol in doses of 75 cc. is a dangerous procedure, as the long continued bombardment of the reticulo-endothelial system by radioactivity will cause undesirable changes.

S.: The Occurrence of Malignancy in Radioactive Persons: A General Review of Data Gathered in the Study of the Radium Dial Painters, with Special Reference to the Occurrence of Osteogenic Sarcoma and the Interrelationship of Certain Blood Diseases, *Am. J. Cancer* 15: 2435-2516 (Oct.) 1931.

3. Martland, H. S.: Occupational Poisoning in the Manufacture of Luminous Watch Dials, *J. A. M. A.* 92: 466-552 (Feb. 9) 1929.

CONCLUSIONS

One clinical dose of thorium dioxide sol (75 cc.) gives the gamma ray equivalent of 1.37 micrograms of radium. Two micrograms of radium has produced symptoms of radium poisoning. Half of the total dose is found in the liver after death, with a large amount in the spleen and traces in the long bones.

All determinations made in this work are in close accordance with those stated in a report of the Council on Pharmacy and Chemistry of the American Medical Association.⁴

The Heyden Chemical Corporation supplied the thorium dioxide sol, stabilized (Thorotrast): Dr. Hillyer Rudisill, gave the author helpful suggestions. Roe E. Remington, Ph.D., prepared the ash.

ESOPHAGEAL STRICTURE DILATED WITH UROLOGIC INSTRUMENTS

HENRY B. FREIBERG, M.D.

CINCINNATI

Since the turn of the century the practice of medicine has become more and more a highly specialized profession. While the vast majority of physicians are still general practitioners, an ever increasing number of them are devoting their time, attention and skill to some highly specialized phase of medical practice. It is undoubtedly this extreme specialization that has stimulated the advances in medicine as they are known today.

Extreme specialization, however, is easily conducive to narrow medical thinking. It is a simple thing for one who practices a very limited field of medicine to direct his thoughts and mental processes only in that certain field of medicine and to neglect, either consciously or unconsciously, the other phases of medicine as well as the patient as a unit. While there is a very definite and necessary as well as useful place in medicine for specialization, the dangers associated with this must be avoided. These dangers are primarily the treatment of a disease or disease condition or the treatment of some organ or group of organs of the body, without the realization that it is the patient who presents complaints and not a disease condition or a diseased organ.

Regardless of the specific complaint of the patient or of the illness that he presents, there is the prime necessity for bearing in mind the interrelationship and the interdependence, as well as the necessity for intimate cooperation, between specialists in their various fields of endeavor.

Fig. 1.—Stricture of esophagus, with dilatation above stricture.

4. Thorotrast, report of the Council on Pharmacy and Chemistry, *J. A. M. A.* 99: 2183 (Dec. 24) 1932.

Read before the annual meeting of the North Central Branch of the American Urological Association, Rochester, Minn., in November 1935.

The treatment of esophageal strictures is primarily the domain of the otolaryngologist. Esophageal strictures occur most frequently following the ingestion of lye, corrosive materials and some poisons, usually taken accidentally or with suicidal intent. Nature and the Almighty cooperate to thwart the desires of many of these individuals, and instead of passing to the hereafter in a peaceful manner they are forced to remain on this earth and suffer physical disabilities that make their lives more miserable than previously.

Fig. 2.—Severe cicatricial stenosis of the esophagus with pocket formation. Annular stricture in the upper half; tubular in the lower section. Preparation of the Pathologic-Anatomic Institute of Vienna.

With the development of the stricture of the esophagus there is an increasing inability to swallow solid foods, and this is soon followed by an inability to swallow even liquid foods or fluids, and finally, with the development of a very dense, tightly contracted stricture, there is an inability to swallow even water. It is unnecessary for me to give a picture of the pitiful state of these patients. The otolaryngologist attempts to treat them by dilation and bouginage of the strictures from above. However, with the development of a dense, almost impermeable stricture, he is unable to introduce even the finest of instruments past this stricture of the esophagus. The next step consists of the performance of a gastrostomy with the formation of a gastrostomy opening to the

skin of the abdomen. This enables one to feed a patient through the gastrostomy wound.

At the same time efforts are made to have the patient swallow a string. If this effort is successful the string is recovered through the gastrostomy opening and it is followed by sounds of increasingly large caliber. Since

Fig. 3.—Cystoscope introduced into the stomach through the gastrostomy opening. Ureteral catheter seen issuing from the patient's mouth. The patient is not anesthetized.

many of these patients are children who are highly uncooperative or adults with negativistic attitudes and since some of these strictures are absolutely impermeable to even a string, the chances of dilating the stricture from above are practically nil.

As the stricture becomes more impermeable, retention of food and of liquid becomes evident in the

esophagus above the stricture, causing dilatation of that portion of the esophagus (fig. 1). As a result of this dilatation it becomes impossible for the otolaryngologist to find the upper end of the opening of the stricture. Because of the convergence of the esophageal folds and the formation of pouches and sacculations in this dilated esophagus, attempts to find an opening through which a sound or bougie can be passed from above are frequently unsuccessful (fig. 2).

In a discussion of this problem with Dr. Samuel Iglauer,¹ professor of otolaryngology at the University of Cincinnati College of Medicine and the Cincinnati General Hospital, it was suggested that a cystoscope be introduced into the stomach through the gastrostomy wound, the stomach filled with water and an attempt made to pass a ureteral catheter retrograde up the esophagus. This was done. Our technic is as follows: The stomach is thoroughly prepared by frequent washings prior to the examination. The stomach is filled with water through the gastrostomy opening and a cystoscope is introduced into the stomach (fig. 3). One

Fig. 4.—Cardia of stomach, depicting convergence of rugae toward esophageal opening. Ureteral catheter entering esophagus.

can observe the various regions of the stomach, especially the cardia. In this region one sees the folds of the stomach converge to a central point, which represents the esophageal opening (fig. 4). One then feeds a ureteral catheter through this opening and if the attempt is successful this catheter traverses the esophageal stricture and soon appears in the mouth (figs. 5 and 6). A string is then fastened to the ureteral catheter and the catheter is withdrawn, thus enabling one to recover the string through the gastrostomy wound. The treatment from this point on again becomes otolaryngologic.

The advantages of dilating the stricture from below are threefold: First, the method just described may be the only one by which any instrument can be made to traverse the esophageal stricture. Second, there is much less danger of puncturing the esophagus and causing a mediastinitis with its sequelae. Third, since a ureteral catheter is flexible it can follow the contour of the stricture, which is almost always fusiform or spiral.

REPORT OF CASES

CASE 1.—M. W., a white girl, aged 3 years, swallowed some lye soap seven weeks before admission to the Children's Hospital. The mother immediately gave the child an emetic. For the next four weeks the child vomited occasionally after eating. During all this time there was an increasing feeling of malaise, and during the following three weeks the child vomited almost

Fig. 5.—Ureteral catheter traversing lumen of esophagus.

all the food eaten. The child was admitted to the hospital, July 8, 1934. While in the hospital vomiting persisted even with a liquid diet. X-ray studies and esophagoscopy showed a complete stricture at the juncture of the upper and middle thirds of the esophagus. Gastrostomy was recommended by the otolaryngologic service. July 17, gastrostomy was performed. A string could not be made to pass the stricture from above. Repeated x-ray films showed a shot at the end of the

string to be lodged just above the stricture. September 26 a cystoscope was introduced into the water-filled stomach and a ureteral catheter was passed up and recovered in the mouth, and from that time on the esophagus was regularly dilated up to size 22 French. The child was discharged March 26, 1935, in excellent condition.

CASE 2.—R. A., a Negro girl, aged 4 years, admitted to the Cincinnati General Hospital, Nov. 13, 1931, had swallowed some lye four weeks before admission. Her mouth was sore for a week and then she complained of an inability to swallow solid foods. There was no vomiting. This was followed by an increased inability to swallow liquid foods and then by vomiting and dehydration. On admission, attempts to have the child swallow a string were unsuccessful. December 2, esophagoscopy revealed several dense scars on the upper third of the esophagus through which the esophagoscope could be passed. In the lower third was an impassable scar. Dr. Iglauer advised gastrostomy and retrograde dilation. Gastrostomy was performed December 8. Feb. 9, 1932, a cystoscope was introduced into the water-filled stomach and a ureteral

Fig. 6.—Ureteral catheter having been introduced through lumen and stricture of esophagus and shown appearing in mouth.

catheter was passed upward to the pharynx. Successful dilation of the strictures followed. March 2 the child pulled the string out and refused to swallow another. March 16 a cystoscope was introduced into the stomach as described previously and was again followed by successful dilations. The patient was discharged Jan. 27, 1933. Follow-up examinations, which included fluoroscopy, failed to demonstrate any destruction or constriction in the esophagus.

CONCLUSION

1. In cases of esophageal stricture in which dilations from above are impossible, the use of a cystoscope through a gastrostomy wound, with retrograde bouginage of the esophagus with the use of a ureteral catheter, is a practical procedure.
 2. Eight patients have been treated in this manner with seven successful results.

PREGNANCY COMPLICATING SUBACUTE BACTERIAL ENDOCARDITIS

REPORT OF A CASE WITH IMMUNOLOGIC STUDIES

JOSEPH FELSEN, M.D.
HENRY SCHUMER, M.D.
AND
A. G. OSOFSKY, M.A.
NEW YORK

Our purpose in this report is to present the clinical, bacteriologic, pathologic and immunologic observations in a case of subacute bacterial endocarditis complicated by pregnancy. Death of the mother occurred sixteen days after the delivery of a full term healthy infant.

Pregnancy complicating subacute bacterial endocarditis is of infrequent occurrence. Croom¹ reports six cases in the literature up to 1906. The subject is further reviewed by Cameron,² and Walser³ in 1928 adds two cases of his own in one of which the mother gave birth to a healthy infant. Our chief concern in the present communication is to explain, if possible, the immunity of the fetus to the infection, which was definitely demonstrated to be a septicemia in the mother during the entire ninth month of gestation.

REPORT OF CASE

C. A., a woman, aged 25, was admitted to the Bronx Hospital Jan. 3, 1936, during the eighth month of her pregnancy. The chief complaints were cough and fever of three weeks' duration. There was no history of a previous rheumatic infection. On physical examination the patient did not appear acutely ill or indisposed, except for slight orthopnea. The uterus was enlarged to a degree corresponding approximately to the stage of gestation stated. The area of cardiac dullness was somewhat enlarged to the left, but no abnormal pulsations or thrills were noted. There was no edema or signs of congestive cardiac failure. Over the left side of the precordium and at the apex there was heard a soft, long, blowing systolic murmur, which was transmitted to the left. There was a low pitched systolic murmur over the aortic area and a suggestive presystolic murmur at the apex. The rhythm was regular and the blood pressure 155 mm. systolic, 60 diastolic. Taken in conjunction with the electrocardiograms, which revealed no axis deviation, the diagnosis of a combined mitral and aortic lesion was made (Dr. L. A. Kapp). On the day following admission (January 4) a positive blood culture was obtained (*Streptococcus viridans*). This was repeated January 10, the blood containing 400 colonies per cubic centimeter. Fluoroscopic examination January 6 showed a moderate enlargement of the left auricle and ventricle, the cardiac outline suggesting mitral and aortic disease (Dr. William Snow). The sedimentation rate of the erythrocytes was accelerated, being 18 mm. in sixteen minutes January 4 and 18 mm. in nine minutes January 13. The temperature ranged between 98 and 100 F. The patient was permitted to return to her home January 15 but was kept under

Dr. Meyer Rosensohn and Dr. Harry Aranow, attending obstetricians, cooperated in carrying out these studies.

observation. She was readmitted January 26, at which time her temperature was 101.6 F. Induction of labor was considered inadvisable, as it was felt that no additional danger to either the mother or the baby was entailed by waiting (Dr. Harry Aranow). January 29 the mother went into labor and was delivered of a healthy, male infant weighing 5 pounds 11 ounces (2,581 Gm.). The following day pain suddenly developed in the right foot, which appeared livid and felt cold. By January 31 the entire right leg was affected, the thigh being somewhat swollen (circumference 49 cm. as against 47 cm. on the left

Fig. 1.—Area of dry gangrene involving the lower portion of the leg and entire foot due to embolism.

side). Pulsation could be felt in the femoral artery but none in the popliteal, posterior tibial or dorsalis pedis. A diagnosis of embolism of the right popliteal artery was made. February 4 a line of demarcation was clearly visible at a point approximately 7.5 cm. above the external malleolus. Below this line the skin was bluish, and a necrotic area 2.5 by 3.7 cm. was noted on the plantar surface of the right foot near the bases of the first and second metatarsal bones. In view of the progressive nature of the gangrenous lesion amputation was advised (Dr. J. L. Amster) but the patient refused operative intervention. February 3 typical embolic lesions (Roth spots) in both fundi were noted (Dr. Nathan Goodfriend). Supplementary laboratory examinations revealed the following:

Blood culture revealed *Streptococcus viridans*, 300 colonies per cubic centimeter, January 27, 150 colonies January 31 and 150 colonies February 6.

The blood count, January 27, showed hemoglobin 59 per cent; erythrocytes 3,400,000 per cubic millimeter; leukocytes 10,100 per cubic millimeter; mature polymorphonuclears 78 per cent, band forms 10 per cent, small lymphocytes 10 per cent, monocytes 2 per cent.

Eight examinations of the urine revealed some albumin and casts, but no erythrocytes. The absence of erythrocytes is of interest since embolic lesions were noted in the kidney sections.

The Wassermann and Kahn reactions were negative.

February 5, cultures of the breast milk, throat and urine yielded *Streptococcus viridans*.

Chemistry of the blood January 4 and January 27 showed dextrose 98.6 and 87.4; urea nitrogen 12.1 and 11.9; uric acid 3.8 and 3.4; creatinine 1.59 and 1.29.

Laboratory examinations of the baby revealed the following: Blood cultures: January 29 (at birth): Blood from the umbilical vessels was sterile. February 3: Blood from the superior longitudinal sinus was sterile. The blood count showed: hemoglobin 90 per cent; erythrocytes 4,700,000 per cubic millimeter; leukocytes 22,700 per cubic millimeter; mature polymorphonuclears 28 per cent, band forms 4 per cent, small lymphocytes 52 per cent, monocytes 16 per cent.

The temperature of the mother before delivery varied between 98.6 and 102 F. Three days after delivery the general trend was slightly higher, but the curve was at no time of the septic type. For five days preceding death, which occurred February 14, the temperature fluctuated between 102 and 104 F. The baby's temperature was normal throughout the twenty-four days of hospitalization.

Examination of the placenta shortly after delivery revealed no essential pathologic changes. Cultures of the blood in the umbilical vessels taken by aspiration through the seared surface of the umbilical cord proved sterile.

Permission for a limited necropsy was obtained. The relevant observations were as follows:

Skin.—A few scattered petechiae were present on the abdomen and chest. There was an area of bluish discoloration with a clear line of demarcation circumscribing the right leg at a point 7.5 cm. above the external malleolus. The toes and heel were black and appeared to be completely gangrenous. The surface was dry, the toes shrunken and an oval area of necrosis was seen on the outer aspect of the small toe. A similar area, 2.5 by 3.7 cm., was noted on the plantar aspect of the right foot at the bases of the first and second metatarsal bones.

Heart.—The heart measured 14 by 9 cm. The maximum thickness of the left ventricle was 11 mm.; that of the right ventricle was 3 cm. The aortic cusps were almost completely destroyed by a large, fungating, friable, dark red vegetation which extended upward on the interauricular septum perforating it and appearing on the mesial aspect of the right auricle. The destructive process continued downward, involving the interventricular septum, which was completely penetrated in its upper portion, where a small perforation was visible. A crushed fragment of the vegetation showed gram-positive cocci in chains. There was a small localized area of pericarditis of recent origin near the division of the right coronary artery.

Kidneys.—The right kidney measured 10 by 4 cm., the left 10 by 5 cm. Several yellowish white infarcts were present near

Fig. 2.—Large fungating destructive vegetation involving all the aortic cusps. Streptococci were present in a crushed fragment.

the surfaces of both kidneys, the largest being 2 cm. in diameter. These were visible on the surface of each kidney as irregular, depressed, firm, whitish areas.

Spleen.—The spleen was 14 by 6 cm. in size. Two wedge-shaped infarcts of a whitish hue were present at the surface, which was depressed at these points. The largest infarct measured 2 cm. in its broadest diameter.

Uterus.—The uterus was 7 cm. in diameter. The placental site was still evident at the fundus, but the general appearance was that of a normally involuting uterus.

Histopathologic Changes.—Sections of the myocardium showed no Ashchoff lesions. There were both recent and old areas of productive pericarditis. In the kidneys many Baehr-Löhlein lesions were found and in the zones of infarction focal abscesses were present. The spleen showed typical infarct formation with hyaline thrombi in the splenic sinusoids throughout the section. In the placenta there was no evidence of placental necrosis or infarction, but in the epithelium covering some of the chorionic villi were seen small scattered chains of streptococci. The organisms appeared to be limited to the epithelium and were located entirely within the poorly defined cell outlines.

THEORETICAL CONSIDERATIONS

We are confronted here with the picture of *Streptococcus viridans* bacteremia in pregnancy with no obvious manifestations in the new-born child. The question of outstanding academic interest is the determination of the mechanism which protected the infant against an infective process of sufficient severity to prove fatal to the mother.

The apparent natural immunity of infants up to the age of 6 months to scarlet fever, diphtheria and poliomyelitis has been frequently demonstrated by many investigators. Ruh and McClelland⁴ have shown in a series of ninety-five cases that mothers and infants gave corresponding reactions to the Schick test with but few exceptions. Similarly von Groer and Kussowitz⁵ reported that in 143 mothers and infants 84 per cent contained equal amounts of circulating antitoxin. Reports confirming these facts were also made by Zingher,⁶ Polano⁷ and Kuttner and Ratner.⁸ The fact that placental serum was capable of blanching the rash in scarlet fever was demonstrated by Toomey and August,⁹ while Aycock and Kramer¹⁰ showed that there was a complete correspondence of neutralizing poliomyelitis antibodies in ten out of twelve mothers and infants. Similar results in six cases of *Clostridium tetani* carriers were reported by Tenbroeck and Bauer.¹¹

McKhann and Chu¹² studied the presence of antibodies in placental extracts. They were able to demonstrate qualitatively antibodies for diphtheria, scarlet fever, poliomyelitis and measles in these extracts of placental tissues. The following mechanisms were postulated by them for the production of this immunity:

1. Transplacental transmission of (a) antigen from the mother resulting in active intra-uterine immunization and (b) antibodies from the mother giving passive intra-uterine immunization.

2. Transmission of antibodies from mother to infant through colostrum and milk.

3. Tissue immunity of the rapidly growing infant.

A fourth possible mechanism may be added. The normal human placenta may be so morphologically constituted that it acts as a filter for bacterial or other infective agents without the presence of antibodies in the infant. The theory most commonly accepted is that the immunity in the new-born results from a passive

transfer of antibodies, mainly through the placenta. In this connection it is of interest to note the observations of Slemmons¹³ in three cases of placental bacteremia. In one case streptococci were demonstrable in the vessels on the fetal surface of the placenta and in the umbilical vessels. In another the organisms were found in the placenta and cord and in the wall of the vein, but none were recovered from the fetal organs. The chorionic epithelium was always intact, no bacteria being found on the surface or in the interior of the villi. Slemmons therefore concluded that infection did not occur from the maternal circulation and pass through the walls of the villi but that entrance was effected through the amniotic membrane with infection of the amniotic fluid.

Fig. 3.—Chorionic epithelium containing small chains of streptococci (arrow).

In the case under discussion here, two of the proposed mechanisms may be eliminated. In the first place, since the infant was never breast fed, the passage of antibodies through the colostrum or milk, as demonstrated by Kuttner and Ratner,⁸ need not be considered. For the same reason the finding of *Streptococcus viridans* in the breast milk was not a factor. Secondly, since blood cultures of the infant were repeatedly sterile, there was no occasion for the development of an active immunity in the new-born. These cultures were taken under aseptic conditions from the umbilical vein and from the superior longitudinal sinus in the infant within a short time after birth. Sterile blood cultures, however, do not necessarily preclude the setting up of an active immunity. The possibility of bacterial metabolites passing through the placenta into the circulatory system of the infant still exists. These by-products of bacterial metabolism or even nonviable micro-organisms may act as specific antigens for the creation of protective antibodies. These are all factors that must be

taken into consideration. In the studies presented we attempted to determine the presence of humoral antibodies in the new-born and the possible rôle played by the placenta in checking the transmission of the infection to the infant.

Methods.—The bactericidal power of the mother's and infant's serum was tested in the manner to be described. This method was also utilized in experiments involving the various placental extracts. It was felt

TABLE 1.—Comparative Bacteriolytic Powers of Mother's and Infant's Serums*

11	1 cc. saline	0.5 cc.	0.5 cc. 1:10	4+
12	1.5 cc. saline	0.5 cc.	0	4+

* In the table 0 indicates no growth; +, less than 20 colonies; 2+, less than 100 colonies; 3+, sparse growth (more than 100 colonies); 4+, heavy growth (colonies confluent).

that the bactericidal titers would render a truer picture of the actual in vivo process than agglutination tests, since the correlation between the quantity of agglutinins demonstrable and the actual immunity present in the host are not always parallel. Also, the tendency to auto-agglutination which existed in the strain of Streptococcus viridans used in the experimental work prevented an accurate determination of the agglutinin titer.

The actual set-up in the tests is detailed in the tables. To 1 cc. of the diluted serum or placental extract was added 0.5 cc. of fresh guinea-pig serum diluted 1:10 and 0.5 cc. of an eighteen-hour blood broth culture of the organism Streptococcus viridans. The tubes containing these mixtures were incubated in the water bath at 37 C. for four hours, during which time they were frequently shaken. Immediately after incubation a standard size loopful from each tube was streaked on a blood agar plate. These plates contained 5 per cent sterile rabbit blood plus 2 per cent dextrose and the prepared mediums were tested for sterility before use.

Although a quantitative determination of the bacteriolytic action was not made, the differences in growth, recorded in the accompanying tables, were easily discernible and the possibilities for subjective errors were thus greatly lessened.

Materials.—Organism: Streptococcus viridans. This strain was obtained from the blood culture of February 6.

Alexin: Fresh guinea-pig serum diluted 1:10. Pooled serums were used in all tests.

Serums: These were obtained from both the mother and the infant during the week following delivery.

Saline Solution: A 0.85 per cent solution was used throughout.

Placental Extracts.—The placentas received directly from the delivery room were washed in running cold water to remove the superficial blood and debris. The excess water was then drained off. A weighed portion of this tissue was macerated with sand in a mortar. The

ground tissue was then taken up in sterile saline solution to make up a 20 per cent suspension. The material was allowed to extract overnight at icebox temperature. Sterile Seitz filtrates of these preparations were used in the tests and designated as saline extracts.

The alcoholic extracts were prepared as follows: The preliminary steps were identical with those just described. The macerated tissue was taken up with alcohol-ether mixtures (3 parts of 95 per cent alcohol plus 1 part of anhydrous ether) to make up a 20 per cent suspension. This preparation was extracted overnight at icebox temperature, then filtered. The clear filtrate was evaporated to dryness at a temperature not exceeding 37 C. The sediment was then taken up in saline solution up to the original volume and passed through a Seitz filter. All extracts were bacteriologically sterile when used.

Results.—The results obtained in testing the bactericidal properties of the serums and placental extracts are recorded in the accompanying tables. A comparison of the mother's and infant's serums as shown in table 1 indicate a transplacental transmission of the humoral antibodies without a diminution in quantity. Both serums showed lytic action in a dilution no higher than 1:200.

The extracts of the mother's placenta showed definite lytic properties. With the saline extract the titer was 1:160, while with the alcoholic preparation the titer was practically the same; i. e., 1:200. These titers appear the more significant when contrasted with the almost complete absence of bactericidal properties in any of the three normal placental extracts. While with the saline extract of the mother's placenta there was complete inhibition of growth in dilutions of 1:20 and

TABLE 2.—Bacteriolytic Properties of Placental Extracts from Patient and from One Normal Control

20	Alcoholic extract 1 cc. 1:800	0.5 cc.	0.5 cc. 1:10	4+
21	1 cc. saline	0.5 cc.	0.5 cc. 1:10	4+
22	1.5 cc. saline	0.5 cc.	0	4+

1:40, there was but partial inhibition in a dilution of 1:50 with but one of the three extracts of the normal placentas.

It should be noted that in the preparation of the placental extracts it was practically impossible to remove the traces of blood. Since the mother's blood showed lytic antibodies, it might be inferred that this remaining blood serum in the placenta accounted for the positive results in the extracts of the mother's placenta as compared with the normal controls. That this inference is

not of great validity can be demonstrated in this manner. The titer of the serum was 1:200 (table 1). The titer of the mother's placenta was 1:160 with the saline extract and 1:200 with the alcoholic extract. Since these last two dilutions were prepared from 20 per cent suspensions, it is easily computed that the actual dilution of the placenta was 1:800 with the saline extract and 1:1,000 with the alcoholic extract. Also, when it is considered that a good part of the blood in the placenta was washed out, the effect of the humoral antibodies in the placental extracts appears negligible.

CONCLUSIONS

1. The clinical, bacteriologic and pathologic changes typical of subacute bacterial endocarditis in a case here presented were complicated by pregnancy.
2. Immunologic studies indicate (a) that the bacteriolysins present in the mother's serum for this strain of *Streptococcus viridans* were transmitted to the infant

The Time Inevitably Comes.—In our present day when so great emphasis is being laid on keeping people well by periodic health examinations and preventive medicine, all this about medical practice may sound very old fashioned. But say what one will, the time inevitably comes to each and every one, now in the best of health, when he must needs cry out for some experienced and sensible doctor who can alleviate if not cure his particular ailments, be they physical or mental; and the kind of sagacity and resourcefulness he will expect and need is less laboratory born than bred of long and sympathetic familiarity with the anxieties and complaints of ailing, damaged, and worn-out human beings.—Cushing, Harvey: *Consecratio Medici and Other Papers*, Boston, Little, Brown & Co., 1928.

METASTATIC TUMOR OF THE HEART

A CASE DIAGNOSED DURING LIFE

MAURICE A. SCHNITKER, M.D.

AND

ORVILLE T. BAILEY, M.D.

BOSTON

New growths in the heart, either primary or secondary, are relatively rare. In the statistics compiled by Mead,¹ primary neoplasm of the heart occurred in 0.03 per cent and secondary in 0.5 per cent of all autopsies. The infrequency of metastatic neoplasm of the heart has been attributed to the rapid cardiac vascular flow and to the nature of cardiac muscle, a medium unsuited to tumor growth.² The literature on the subject to 1930 has been thoroughly reviewed by Yater³ and since then by Mead¹ and by Gilchrist and Millar.⁴

The diagnosis of either primary or metastatic tumor of the heart has seldom been made before death. Primary tumor of the heart has been recognized during life three times⁵ and metastatic tumor five times.⁶ The antemortem diagnosis of pericardial metastasis has been made twice.⁷

The symptoms of cardiac tumor have been classified by Fishberg⁸ and Yater.³ These authors emphasize the presence of signs and symptoms of heart disease, difficult of interpretation and not responsive to the usual therapy. There is no pathognomonic sign or symptom of cardiac tumor. However, three features, any one of which might suggest the clinical diagnosis, are heart block, arrhythmias or symptoms and signs of cardiac insufficiency without apparent cause in a patient with a known malignant process, and the accumulation of bloody fluid in the pericardial sac. It is to be stressed that very extensive involvement of the heart may occur without any disturbance of its function. A series of fourteen instances of metastatic tumor of the heart has been reported in which no case showed any symptoms of cardiac involvement during life.⁸ As Gilchrist and Millar⁴ state, "the most characteristic feature [of cardiac tumor] is the inability to ascribe a satisfactory etiological cause for the obvious signs of organic heart disease."

Metastatic tumor of the heart may occur from a primary source in any organ of the body by hematogenous or lymphatic routes or by direct extension. It

is stated, however, that the heart is seldom involved by continuity from neighboring organs.⁹ Pic and Bret¹⁰ first stressed the association of cardiac neoplasm with primary or secondary intrathoracic tumors. According to Mead,¹ extension into the heart from primary pulmonary carcinoma occurs in 0.26 per cent of cases, indeed a rarity in view of the relative infrequency of bronchogenic neoplasm.

The present communication concerns a patient in whom cardiac disturbances developed resulting from metastatic carcinoma of the heart, which was diagnosed clinically. The primary tumor was in the right main stem bronchus and reached the heart by direct extension, with associated auricular flutter. Only one other instance of auricular flutter resulting from cardiac metastasis has been diagnosed ante mortem, that one from a reticulum cell sarcoma of cervical lymph nodes (Fishberg's⁶ case 3). A case of congenital rhabdomyoma of the heart¹¹ and another of metastatic tumor of the pericardium¹² had associated auricular flutter, but the neoplasms were not recognized in either instance during life. In the 3,570 autopsies performed in the Peter Bent Brigham Hospital (1913-1936) there have

Fig. 1.—Upper tracing, taken July 27, 1936: auricular flutter present on admission. Middle tracing, taken August 3: nodal rhythm present on the eighth hospital day, following six days of normal sinus rhythm after the cessation of flutter. Lower tracing, taken August 5: partial heart block.

been in all nineteen instances of cardiac neoplasm, an incidence of 0.53 per cent. None of these except the one here reported were recognized during life. One instance of primary tumor of the heart has been included in this series of autopsies. It has been described elsewhere.¹³

REPORT OF CASE

History.—M. S., a man, aged 64, German, a chef, admitted to the hospital July 27, 1936, complained of shortness of breath, cough, swelling of the ankles and loss of weight and appetite.

Two and a half years previously a cough developed, which persisted and became worse in the few months before entry. At the time of admission he was producing a cupful daily of white, frothy sputum. On one occasion, three or four months before, there was blood streaking of the sputum. For nine months dyspnea had been present, first on exertion and later at rest. There had been some wheezing for days at a time but not occurring in definite attacks. He never had pain in the chest. For the past year he had had anorexia, insomnia and a loss of 58 pounds (27 Kg.). For two and one-half months he had noticed attacks of palpitation of the heart of a few seconds' duration. Two weeks before entry swelling of the ankles occurred, which prompted him to enter another hospital. There a heart rate of 176 was recorded but without mention of the type of rhythm. He was transferred later to the Peter Bent Brigham Hospital for further study.

Examination.—The patient was well developed and fairly well nourished but very apprehensive and orthopneic. There was slightly more fullness of the right supraclavicular fossa than of the left. The trachea was deviated to the right. Rapid, regular pulsations could be seen in the distended veins of the neck. The heart was moderately enlarged; there was a scratching quality to the sounds, but no murmurs were heard. The rate was regular at 176 per minute, temporarily slowed to just half that rate by right carotid sinus pressure. Blood pressure was 80 mm. of mercury systolic, 60 diastolic. The right side of the chest was diminished in excursion. Posteriorly it was dull to percussion throughout and accompanied by absent breath sounds and diminished tactile fremitus to the level of the angle of the scapula. A few fine râles were present over the apex. Anteriorly there was dullness and absent tactile fremitus below the level of the third rib. The left lung presented a few râles at the base. The hands were cyanotic and edematous, the left more than the right. The fingers showed definite clubbing. There was marked soft pitting edema of the feet and ankles. The hemoglobin was 75 per cent (Sahli); erythrocytes numbered 4,580,000 and white blood cells 10,400 per cubic millimeter of blood. The Wassermann and Hinton reactions for syphilis were negative. No tumor cells were seen in the sputum.

An electrocardiogram taken immediately after examination confirmed the presence of auricular flutter (fig. 1, upper tracings). A thoracentesis on the right side yielded 1,800 cc. of straw colored fluid with a specific gravity of 1.020, containing 1,300 red blood cells and 1,600 white blood cells per cubic millimeter. No tumor cells were found. In the first twenty-four hours he was given 1.4 Gm. of digitalis folia by mouth. The auricular flutter changed to a normal sinus rhythm with a rate of 104. On the third day a second thoracentesis was done with the removal of 1,100 cc. of sanguineous fluid with a specific gravity of 1.017, containing 47,000 red blood cells and 100 white blood cells per cubic millimeter. Tumor cells were demonstrated in the sediment studied in paraffin sections. The presence of tracheal displacement toward the side of the chest containing so much fluid suggested atelectasis of a portion of the right lung, further evidence of probable neoplasm occluding a bronchus. By the fourth day the swelling of both hands had extended to involve the forearms, and there was visible edema of the face and neck. A portable roentgenogram of the chest showed tracheal deviation, and a hydropneumothorax to the fifth rib posteriorly, practically obscuring the right lung field so that the presence or absence of carcinomatous growth could not be determined.

With this evidence a clinical diagnosis was made of carcinoma of the right bronchus, with involvement, probably by direct extension, of the right auricle and superior vena cava as an explanation for the disturbances of cardiac rhythm, and the edema of the face, neck and forearms.

On the eighth hospital day, additional electrocardiograms showed nodal rhythm (fig. 1, middle tracings), and two days later partial heart block (fig. 1, lower tracings). On the twelfth day the patient was seen by Dr. Lyman Hoyt, visiting physician to the hospital, who independently suggested that "with a probable malignancy in the lung and the evidence of disease in the heart, because of the many different rhythms, one might suspect malignant metastases to the heart from the lung."

In the first three weeks seven thoracenteses were performed, with removal of a total of 5,875 cc. of fluid. In all but the first instance the fluid was sanguineous. Four of these seven specimens showed tumor cells in paraffin sections of the sediment. Intensive roentgen therapy to the chest was begun, but fluid continued to accumulate so that thoracenteses were necessary every three or four days. After receiving a total of nine roentgen treatments, totaling 2,700 roentgens, he seemed somewhat more comfortable for the next week. On the thirty-first day the electrocardiograms showed delayed auriculoventricular conduction and premature ventricular beats. Edema of the arms and pleural effusion persisted. The patient became progressively worse and died somewhat unexpectedly on the thirty-fifth day in the hospital (August 30).

Autopsy.—The anatomic diagnoses were bronchogenic carcinoma of right primary bronchus with extension into the right auricle and superior vena cava; metastasis to the epicardium and right pleura; thrombosis of innominate and subclavian veins on both sides; pulmonary atelectasis on the right; bronchopneumonia on the left, and acute bilateral pleuritis.

The right primary bronchus was completely occluded by a white, soft, friable tumor mass 1.5 cm. from its origin. Section showed that the tumor mass was 9 cm. in diameter. It replaced almost completely the middle lobe and extended for a short distance into both upper and lower lobes, with resultant atelectasis. The tumor also extended by way of the mediastinum to involve the right auricle and the mouth of the superior vena cava. The right pleural cavity contained 500 cc. of sanguineous, slightly turbid fluid. There were many fibrous adhesions between the parietal and visceral pleurae. When these were broken a gelatinous layer of metastatic tumor was found over the visceral pleura. The left pleural cavity contained 200 cc. of similar fluid but there was no evidence of metastatic tumor. The left lung showed an early bronchopneumonia in both lobes.

The pericardium showed a moist, glistening surface. On the posterolateral aspect of the heart near the origin of the pulmonary artery there were multiple small nodules of firm, white tumor tissue averaging 3 mm. in diameter on the visceral layer of the pericardium. Another similar nodule was found overlying the anterior wall of the left ventricle adjacent to the left coronary artery. As the heart was opened, a mass of tumor measuring 0.7 by 1 cm. was found on the posterior wall of the right auricle in the region of the sino-auricular node. This lay just beneath the endocardium and elevated but did not erode it. Dissection showed it to be continuous with the primary tumor mass in the right bronchus. The remainder of the wall of the right auricle in the region of the mouth of the superior vena cava was firm and rigid because of tumor invasion. As the superior vena cava was followed upward, it was found that the tumor extended into its lumen and occupied most of it at a level 1 cm. above the opening into the right auricle. The mass of neoplasm, irregular in outline, could be followed upward only 0.5 cm. Beyond that point a firm, grayish red thrombus free from tumor was found. This continued so as to occlude both innominate veins. In the subclavian veins the thrombus extended for approximately 2 cm. but did not entirely occlude their lumens.

Histologically, the tumor was a small cell carcinoma. The cells were arranged in masses separated by a small amount of connective tissue stroma. Mitoses were numerous. The tumor, while displaying a distinctly epithelial structure, showed no differentiation into epidermoid or glandular elements. Adjacent to the tumor in the heart, the muscle fibers showed much atrophy with vacuolization and nuclear degeneration.

COMMENT

This case presents an unusual opportunity to follow the development of neoplasm in the heart by repeated clinical studies, electrocardiograms and necropsy. The presence of auricular flutter on admission, with the suspicion of a bronchogenic neoplasm, suggested that there might be encroachment of the tumor growth on the right auricle of the heart. Definite localization was difficult, but with the presence of edema of the hands we thought that the tumor was probably in the region of the superior vena caval opening and possibly disturbing the sino-auricular node. The flutter mechanism allowed us to assume that the auricles were being involved by tumor but it did not allow us to conclude that the sino-auricular node was necessarily involved. Invasion of this region suggested itself first by the edema present and then by the subsequent assumption of the rôle of the pacemaker of the heart by the auriculoventricular node. If the tumor invasion was the cause of the auricular flutter mechanism, it is very striking that digitalis caused this to revert, probably through the sequence of auricular fibrillation, to a normal sinus rhythm. This response to digitalis was similar to that seen in about one third of the instances of auricular flutter associated with valvular or myocardial heart disease. It might have been expected that continued growth of the tumor would have caused recurring attacks of auricular flutter, or perhaps fibrillation, but that did not occur. Possibly the continued administration of digitalis prevented it.

Of further interest is the fact that, after six days of normal sinus rhythm following the cessation of the auricular flutter, auriculoventricular nodal rhythm was shown in the electrocardiogram. It is stated that the auriculoventricular node has its own irritability and rhythmicity.¹⁴ Further, it has been taught¹⁵ that marked depression of the normal pacemaker of the heart (the sino-auricular node) and failure of any other part of the auricular muscle to assume its rôle may cause the auriculoventricular node to take on, at least temporarily, the rôle of pacemaker of the heart. It seems fair to consider that the tumor growth in the right auricle caused depression of the sino-auricular node and that the auriculoventricular node assumed the rôle of pacemaker. It was transient, however, since subse-

Fig. 2.—Section of the wall of the right auricle in the region of the sino-auricular node. The endocardium at the top is intact. A very thin layer of atrophic muscle persists beneath it. Most of the wall of the auricle has been replaced by the carcinoma, which occupies the middle and lower portions of the section. Hematoxylin and eosin, $\times 165$.

quent electrocardiograms showed supraventricular sinus rhythm (fig. 1, lower tracings). These subsequent changes seen in the electrocardiograms served to strengthen the clinical diagnosis of metastatic tumor of the heart.

As shown at autopsy, there was direct extension of growth of tumor into the right auricle, the least frequent mode of metastasis to the heart. Direct extension of pulmonary tumors to the heart have been reported by Geipel,¹⁶ Napp,¹⁷ Morison,¹⁸ Fishberg⁶ (two cases), Yater³ and Mead.¹

The occlusion of the lumen of the superior vena cava by tumor, which is also uncommon, adequately explained the edema of the upper portion of the body. Similar

instances of vena caval occlusion by neoplasm have been reported by Ehrenberg,¹⁹ Binder,²⁰ Fishberg,⁶ Barnes⁵ and Helwig.²¹ To our knowledge, except for the cases reported by Barnes and Fishberg, the finding of edema in those instances did not prompt a clinical diagnosis of such tumor extension. The physical finding of edema of the face and arms in cases of cardiac tumor usually causes the diagnosis of mediastinal tumor to be made.³ The presence of edema of the face and arms, along with the disturbed cardiac rhythm, indicated to us that there was tumor in the region of the opening of the superior vena cava. To be sure, it was impossible to determine whether the superior vena caval obstruction was due to pressure from without or to growth of tumor within its lumen. Necropsy showed the latter to be the case.

SUMMARY

In the case presented, a carcinoma of the right primary bronchus had invaded directly the wall of the right auricle in the region of the sino-auricular node.

The diagnosis of secondary involvement of the heart by neoplasm was made clinically because of development of disturbances of cardiac rhythm in a patient with a carcinoma of the right lung.

The tumor also invaded the superior vena cava with consequent venous stasis of the upper portion of the body.

ALAR SCAPULA

TRAUMATIC PALSY OF SERRATUS MAGNUS

E. J. BERKHEISER, M.D.

AND

FRED SHAPIRO, M.D.

CHICAGO

Although this subject is not new and has been referred to in the medical literature occasionally since Berger's¹ original monograph in 1875, we feel that attention should be again given to it, especially to clarify its etiology and to stress its adequate treatment. This is supported by the fact that at a recent meeting of representative surgeons, a similar case was shown without any suggestions offered as to the proper treatment.

The literature on this subject in regard to its etiology is indefinite, with many of the authors favoring the view that the disability is due to traumatic rupture of the serratus magnus at its scapular insertion. Only one author was able definitely to palpate a hiatus between what he considered the retracted portion of the muscle and the edge of the scapula. Although other authors consider that the long thoracic nerve of Bell may have been injured, their writings lead one to suspect that they favor the theory of laceration of the serratus muscle as the etiologic factor for the deformity in some of their cases.

The positive differentiation as to which factor is directly responsible for this condition is difficult to ascertain clinically because of the inaccessibility of the motor points of the serratus magnus muscle. On electrical stimulation of the long thoracic nerve of Bell in

the cases in which the deformity is due to nerve injury, there will be no response. Likewise, if the muscle is completely torn, such stimulation to the nerve will not cause movement of the scapula. Owing to the difficulty of stimulating the motor points of the serratus magnus muscle, one cannot elicit contractions of the muscle that can be noted by the movements of the scapula to prove complete laceration of the muscle at its scapular insertion. It seems logical to conclude that muscle laceration, if present, should cause in addition to loss of function local tenderness, pain, swelling and at least in some cases superficial ecchymosis after the lapse of a few days, owing to the absorption of the hematoma. These changes were not noted in the four cases we observed and are reporting, nor were they noted in the majority of cases reported in the literature. Furthermore, relatively late conservative treatment of cases due to laceration of the serratus magnus muscle should not result in improvement or cure of the condition.

It is a well known fact that, following an injury to a peripheral motor nerve which does not result in laceration of the nerve, immobilization of the part in a position so that the muscles supplied by the nerve are relaxed favors return of function in the muscle with regeneration of the nerve. Therefore, if cases seen relatively late after the original injury are treated by immobilization in the position of election for relaxation of the involved muscles and result in return of function of the muscles, it is logical to conclude that the injury sustained was to the motor nerve rather than to the muscle itself.

It is our contention that the vast majority of these cases are due to nerve concussion rather than to laceration of the muscle. If this contention is true, it logically follows that immediate active treatment should be instituted in all such cases encountered.

ANATOMY

Eshner,² in a study of the anatomic considerations involved in serratus magnus palsy, was impressed by the following important considerations:

Many large and powerful muscles that control the motion of the shoulder and the upper extremity are attached to the scapula. The trapezius elevates the scapula, causing elevation of the acromial process and outward rotation of the lower angle. The lower angle is rotated medially by the rhomboids. The serratus magnus moves the scapula outward, forward and slightly upward. It rotates the scapula on its inner angle and elevates the acromion, but this motion is opposed by the elevator muscle of the angle of the scapula and the rhomboids. It maintains approximation of the scapula to the thoracic wall. The actions of the different muscles are not simple, but complicated, so that any deficiency that might result from loss of function of any one or more might be in a large measure compensated for by others.

The position of the scapula when the arm is at rest in the presence of paralysis of the serratus magnus is as follows: The scapula is elevated and its inner border is approximated to the vertebral column and directed obliquely upward and outward from below, while the inferior angle exhibits a winglike projection backward and the outer border assumes a more nearly horizontal position. The superficial and long course of the supplying nerve—the long thoracic nerve of Bell—on the side of the neck and chest exposes the nerve to injury in its peripheral course.

1. Berger, C.: Die Lähmung des Nervus thoracicus longus (Lähmung des Musc. serratus antic. maj.). Breslau, M. Cohn & Weigert, 1873.

ETIOLOGY

The common causes of injury are a blow, a fall, pressure from heavy weights or puncture wounds involving the supraspinatus region or compression of the scalenus medius muscle through which the nerve passes or along its course in the axillary space. Excluding trauma, the nerve of Bell may be involved in inflammatory or degenerative processes induced by factors that predispose to rheumatism, such as cold and wet; or inflammation of the long thoracic nerve may develop as a complication to febrile diseases such as typhoid, influenza, diphtheria or puerperal sepsis. The serratus may be involved along with the other shoulder muscles in the muscular dystrophies, in anterior poliomyelitis and occasionally in direct injury to the muscle. Hysterical paralysis of the muscle has been reported.

Although paralysis of the serratus magnus is thought to occur more commonly in men than in women, because of the etiologic factors involved, our four cases in this report have occurred in women. All of these cases being reported occurred in the right shoulder in adults. However, the condition has been noted in children as a result of anterior poliomyelitis.

PATHOLOGY

In our group of cases the essential pathologic condition is deduced to have been a concussion of the long thoracic nerve of Bell followed by degenerative changes in the nerve and atrophy of the serratus magnus muscle. This deduction seems justified because the disability in each of the four cases was noted immediately after the patient sustained a rather severe trauma localized to the right shoulder region and because the resultant disability was cured by a treatment proposed to facilitate return of function to a muscle the motor nerve of which has suffered a concussion.

PATHOGENESIS

In case 1 the disability occurred subsequent to the effort associated with pulling on straps to aid in the bearing down maneuver during childbirth. In this case the nerve was probably injured at the point where it passes through the scalenus medius muscle. In cases 2, 3 and 4 the disability occurred subsequent to a rather severe trauma to the right shoulder region.

SYMPTOMS

The patients were unable to elevate the arm above the horizontal, and when this was attempted the median border of the scapula approached the vertebral spines. If the arm was held horizontally in front, the median border and the inferior angle of the scapula were removed from the thorax and the scapula stood out like a wing, forming a cavity into which the hand could be inserted under the scapula. The arm could be elevated above the horizontal by the accessory muscles, especially if the upper portion of the body was inclined backward or if the inferior angle was rotated downward and outward and if pressure was applied to approximate the scapula to the thorax. There was weakness of the arm and the patients were unable to cross the arms anteriorly or to apply pressure, as in pushing. Pain was invariably associated with the physical disability and was referred to the back and shoulder regions.

TREATMENT

Thomson and Miles³ advised conservative treatment, consisting essentially of strychnine, muscle and nerve tonics (?), massage and faradic stimulation. They sug-

gested the mechanical use of a padded belt for pressure over the scapula to maintain the scapula against the thoracic wall. They consider two methods of operative intervention: (1) transplantation of the latissimus dorsi over the inferior angle of the scapula to diminish the deformity and (2) transplantation of the clavicular origin of the pectoralis major to the serratus magnus or the axillary border of the scapula.

Skillern⁴ treated one case by rest, massage and strychnine and after three months, when no improvement was noticed, advised operative measures. He formulated a procedure whereby the proximal end of the short subscapular nerve was to be anastomosed to the distal end of the sectioned long thoracic nerve of Bell. This procedure was not attempted, as far as we could determine from the literature.

Gower advised the use of an airplane type of splint, faradic stimulation, massage and muscle training. If these measures did not give results, he stated that the

Fig. 1.—Position for relaxation of serratus magnus.

operative procedures advocated by Thomson and Miles or Skillern should be attempted. He reported one case with a successful outcome under conservative measures and four cases with no improvement. He does not state whether operation was performed in any of the unimproved cases.

Eshner² suggested treatment by massage and electricity.

The four cases that we are reporting were not treated with any of the aforementioned medicinal measures, which undoubtedly would have been worth while adjuncts to the treatment instituted. These reported cases were treated by constant immobilization with the arm held so as to relax the serratus magnus muscle. In this position the scapula was held closely approximated to the thoracic wall and this position was maintained by a plaster shoulder spica cast (fig. 1). It was deemed advisable to use the plaster cast instead of a brace so as to have the assurance that the position

would be constantly maintained. It was found that a period of three months was necessary for the return of function to the nerve which was manifested by the ability of the muscle to maintain the scapula in its normal position. After the return of function, physical therapy aids materially in restoration of muscular

Fig. 2 (case 1).—Original deformity in alar scapula.

strength and mobilization of the joints of the upper extremity. All four patients recovered complete function with this method of treatment.

REPORT OF CASES

CASE 1.—Mrs. K., aged 22, when seen, Nov. 12, 1923, stated that she injured the shoulder by pulling on straps during confinement three months previously. She was first conscious of the disability of the right shoulder after the child was born. The disability consisted of a feeling of stiffness and soreness at the top and back of the right shoulder. At first the pain was intermittent but at this time it was constant.

On examination, while she was sitting, viewed from the back, the right shoulder blade rested three-fourths inch higher than the left and the inferior angle approached the vertebral spines. She indicated the top of the shoulder and sternum 2 inches below the manubrium and the lateral surface of the chest wall along the posterior border of the axilla as the tender places. She could not voluntarily raise the arm to the level of the shoulder and in an effort to do so the upper angle of the scapula was apparently elevated by the trapezius and the lower angle would swing far away from the ribs (fig. 2). Passively there was a normal range of motion at the shoulder joint.

November 15 a plaster shoulder spica was applied with the scapula in normal position.

Feb. 14, 1924, the cast on the arm was bivalved for active and passive exercises.

March 6 the remainder of the cast was removed. The patient now has normal range of motion, and although the arm tires more easily than the other the scapula remains in its normal position (fig. 3).

CASE 2.—Mrs. S., April 24, 1932, stated that she fell while scrubbing the floor eighteen months previously and injured her right shoulder. Immediately thereafter she noted pain and disability of the right shoulder and arm. The pain was described as occurring at the top of the shoulder, and it radiated along the lateral aspect of the right side of the chest. The

disability consisted of weakness of the right arm and inability to execute what she considered the normal motions of her arm at the right shoulder.

On examination the right scapula had the characteristic wing-like projection. There was no obvious weakness of the trapezius, supraspinatus or rhomboids. The serratus magnus was atrophic.

May 12 a plaster shoulder spica was applied as described in case 1.

June 11 a felt pad was inserted between the scapula and the cast to assist in holding the scapula against the thorax.

August 13 the cast on the arm was bivalved and physical therapy was instituted.

September 10 the cast was removed. The scapula remained in its normal position.

CASE 3.—Mrs. P., aged 36, seen Jan. 27, 1936, stated that she fell out of a second story window the preceding New Year's eve, striking on her right shoulder. Immediately she noted pain in the right shoulder area and inability to use the right arm normally. Pain and disability were still present at this time.

On examination the essential changes were wing scapula on the right side with loss of function of the serratus magnus.

February 3 a plaster shoulder spica cast was applied, as described in case 1.

May 11 the cast was removed and physical therapy was instituted. At this time the scapula was in normal position and retained its normal position on all active motions of the right arm.

The patient when last seen, October 19, had normal range of motion at the right shoulder with complete recovery.

CASE 4.—Mrs. C., aged 63, when first seen, June 8, 1936, stated that she fell on the sidewalk April 1, 1936, injuring the right shoulder and sustaining a fracture of the pelvis. She had been at complete bed rest since the date of injury, but she stated that although she had no pain referable to the fracture of the pelvis she still had pain and disability of the right shoulder and arm.

Fig. 3 (case 1).—Scapula in normal position after three months treatment.

On examination the right shoulder and arm were essentially normal except for a definite wing scapula.

The right scapula was immobilized by a plaster shoulder spica which, when removed three months later, revealed a complete return of function of the serratus magnus muscle.

SUMMARY

1. Alar or winged scapula can result from nonlacerating injury to the long respiratory nerve of Bell.

2. Alar scapula following trauma is more probably caused by injury of the nerve of Bell than by laceration of the serratus magnus muscle.

3. The prognosis of alar scapula secondary to trauma to the nerve of Bell is better than a study of the literature would lead one to believe, provided the case is adequately treated.

4. Alar scapula is amenable to proper treatment, and good results can be obtained as late as eighteen months after onset of paralysis in traumatic cases.

5. Operative intervention has not been indicated in any of our cases.

6. In the four cases reported, all were treated by the proposed method and all made a complete recovery.

NOTE.—On Oct. 19, 1936, after this article was written, another case of alar scapula was observed by us. Although it is believed to have resulted from inflammatory factors associated with a myositis of the muscles of the neck, which had occurred one year before, we propose to treat this case by the method outlined.

The end result of this type of treatment for alar scapula secondary to inflammatory factors as manifested in this case may be reported at a later date.

CULTURE OF HUMAN MARROW

DETAILS OF A SIMPLE METHOD

EDWIN E. OSGOOD, M.D.

AND

INEZ E. BROWNLEE, B.A.

PORTLAND, ORE.

In previous articles, two methods¹ for the culture of human marrow in bulk were described in a preliminary way and some of the problems that offered promise of solution by marrow culture were outlined. Details of the procedure and of the composition of the mediums were not given because little was then known about them. It is our purpose in this article to describe a technic of marrow culture, which has proved simple and entirely satisfactory for many types of investigation, in sufficient detail so that any one trained in bacteriologic, chemical and hematologic technic can use the method.

It early became evident that there was no such thing as one set of ideal conditions for marrow culture, because growth consists of three distinct phases. These phases are multiplication either by mitotic or by amitotic division, which corresponds to hyperplasia; increase in cell size, which corresponds to hypertrophy in the terminology of pathologists, and maturation, which corresponds to differentiation in the terminology of biologists. Conditions that favored the maximum rate of multiplication did not favor maturation, and conditions that favored the maximum rate of maturation did not favor multiplication. In normal marrow, all three processes take place simultaneously. In addition, there is a fourth process; namely, release of cells from the marrow into the blood stream. It is also evident that, in the marrow of healthy adults, these processes take place at such a rate that multiplication just balances the maturation and release of cells into the blood stream so that there is no significant increase or decrease in the total number or in the relative proportions of any cell type present.

The method to be described, while not producing the maximum rate of multiplication we have obtained or the maximum rate of maturation, does permit the two to occur simultaneously much as in normal marrow. Since it was necessary to determine the proper oxygen and carbon dioxide tension, the p_{H_2} , the volume of fluid per unit number of nucleated cells, the thickness of the layer of fluid over these cells, the optimal frequency of changing the mediums and the gas mixture, the optimal temperature, the speed of centrifugation, and many other factors as well as the composition of the medium, more than 400 experiments² have been performed in the development and investigation of this technic.

DESCRIPTION OF THE METHOD

Preparation.—All transfers of nutrient fluid and marrow are made with sterile syringes and needles through rubber vaccine vial caps, the caps being sterilized each time with 70 per cent ethyl alcohol. Vaccine vials of pyrex or other lead free, insoluble glass are sterilized by dry heat at 150 C. for one hour and capped with rubber caps sterilized by autoclaving or boiling. The single cap type of vaccine vial proved superior to the double cap type at first used. An abundant supply of 50, 30, 20, 10 and 1 cc. syringes should be kept sterile by wrapping in paper and sterilizing in a dry sterilizer at 150 C. for one hour. The 20-22 gage Luer three-fourths inch needles and 19 gage 4 inch needles are dry sterilized in indented test tubes plugged with cotton.

Prepare citrated balanced salt solution and balanced salt solution as given in the table, using water freshly distilled from pyrex glass, and sterilize the solutions immediately after the ingredients are dissolved, either in the autoclave or by passing through a Seitz³ or Chamberlain-Pasteur filter and bring back to volume with sterile water. Store in 50 cc. vaccine vials.

Accumulate a supply of sterile cord serum by aspiration of blood with a sterile 50 cc. syringe and needle from a vein in the fetal side of the human placenta as soon as possible after the cord has been clamped. Introduce this blood into vaccine vials and, after clotting has occurred, centrifugate, withdraw the supernatant serum with a sterile long needle and 50 cc. syringe and, after recentrifugation, store in another 30 cc. pyrex vaccine vial in the icebox, labeled with the date and patient's name or case number. If cord plasma is desired, introduce an equal volume of cord blood into a 50 cc. vial containing 25 cc. of citrated balanced salt solution, centrifugate, draw off the supernatant plasma, recentrifugate, and store in separate vials. This plasma-citrated balanced salt mixture may be used as the medium directly and it is necessary if cells of the thrombocyte series from the megalokaryoblast to the platelet are to be grown. For all other cells, serum seems to serve equally well and has usually been employed.

It will be noted that the composition of the medium is the same as that found by the Geys⁴ to be ideal for the growth of human tumors; but we demonstrated the advantages of this medium for marrow culture by comparison of the balanced salt solution with Tyrode's solution and various other salt mixtures under con-

trolled conditions and by comparison of different concentrations of cord serum with each other, with serum from the subject who donated the marrow, with serum from other healthy adults, and with serum of animals. Any concentration between 10 and 50 per cent of any type of serum tried would support growth but 35 (25-40) per cent human cord serum gave the best growth.

Technic of Sternal Puncture.⁵—Perform the sternal puncture with the patient lying on the back with the shoulders on a firm pillow and the head dropped back. Prepare the area of the sternomanubrial junction with iodine and alcohol and drape the face and shoulders with sterile towels, leaving exposed a triangle about 1 inch on a side over the middle of the sternomanubrial joint. Wearing sterile gloves and using aseptic technic, infiltrate the skin, subcutaneous tissue and periosteum with about 4 cc. of 1 per cent procaine hydrochloride. The landmarks are the jugular notch for the midline of the sternum and the ridge opposite the second ribs for the sternomanubrial joint. After allowing about three

last 300 punctures no failure to obtain marrow. The procedure is so simple and painless that many subjects have volunteered three or four times.

Concentration of Nucleated Cells.—Centrifugate the vial containing the marrow at 1,500 revolutions per minute for fifteen minutes. Withdraw an amount of the supernatant liquid equal to the original volume of citrated balanced salt solution and discard. Mix the cells with the remaining liquid and transfer to a volume index tube⁶ capped with a rubber vaccine vial cap or rubber dam. Centrifugate this at 1,500 revolutions per minute for thirty minutes, withdraw and discard the supernatant fluid, withdraw all the white cell layer and a little of the red cell layer and transfer to a 30 cc. pyrex vaccine vial containing 8 cc. of balanced salt solution. Mix well. This procedure concentrates the nucleated cells of the marrow and gets rid of most of the non-nucleated erythrocytes, which have a tendency to inhibit growth.

Dilution and Addition of Mediums.—Mix thoroughly, withdraw 0.5 cc. and do a total nucleated cell count according to the usual technic⁷ for white cell counts. Dilute the remaining marrow in the vial with the amount of balanced salt solution and cord serum calculated to give a total nucleated count between 1,000 and 2,000 per cubic millimeter and a final concentration of cord serum equal to 35 per cent by volume. Mix thoroughly and subdivide into a series of 30 cc. one-stopper vaccine vials, placing about 12 (from 10 to 15) cc. in each vial. To each of these, leaving one for a control, add a different quantity of a sterile solution, in balanced salt solution, of any substance to be tested,⁸ adding enough balanced salt solution to make the final volumes the same.

Control Counts.—Mix each vial thoroughly, remove 1 cc. for control counts, and put the vials into a 37.5 C. incubator or water bath. On the 1 cc. of well mixed culture removed, do a total nucleated and red cell count, and then centrifugate in a corked small test tube (8 by 50 mm.) supported in cotton in a 15 cc. centrifuge tube. Withdraw the supernatant liquid, leaving only a volume equal to the volume of packed cells, mix thoroughly and make smears, holding the smearing slide at an angle of from 70 to 80 degrees to secure an even distribution. for Wright's and peroxidase stains, make supravital preparations, reticulocyte counts or add vaccine and wait fifteen minutes, remix and make smears to demonstrate phagocytosis. Determinations of p_H and chemical and serologic tests may be done on the supernatant fluid. At any interval desired, remix the cultures thoroughly, withdraw 1 cc. portions and examine in a similar manner. We have usually examined our cultures every twenty-four hours.

Changing the Mediums and Gas Mixture.—Every forty-eight hours, change the mediums by centrifugating the vials containing the cultures at 1,500 revolutions per minute for fifteen minutes, withdrawing the supernatant fluid and replacing it with a volume of 35 per cent cord serum in balanced salt solution equal to the volume of fluid withdrawn. Change the air in the vials about every four days by aspirating filtered air into a 50 cc. syringe and with an extra needle run through the cap for exit of the gas, forcing the fresh air into the vials. The device for obtaining filtered air consists

minutes for the anesthetic to take effect, test the anesthesia with the hypodermic needle used for infiltration and, if complete, introduce the sternal puncture needle (16 gage spinal puncture needle cut off to 3.5 cm. and rebeveled) vertically into the midline of the joint. Then tilt the needle to an angle of from 30 to 60 degrees with the plane of the sternum and, standing at the patient's head, introduce it into the marrow cavity by rotating the needle. Apply very little pressure. When the needle has entered the bone, as judged by its rigid fixation, remove the stylet and attach an absolutely tight 10 cc. syringe. This syringe should previously be tested by drawing the plunger out to the 2 cc. mark and then, with the tip covered by the finger, draw the plunger out to the 10 cc. mark, holding it there for a minute or longer. When released, the plunger should go back to the 2 cc. mark, indicating no leakage of air. With the 10 cc. syringe, aspirate from 1 to 10 cc. of marrow, loosen the syringe from the sternal needle, attach a 20 gage, three-fourths inch needle and introduce the marrow into a 50 cc. vaccine vial containing 25 cc. of sterile citrated balanced salt solution. Release the plunger to allow the displaced air to escape, remove the needle and have an assistant shake the vial vigorously. Replace the stylet in the sternal puncture needle, withdraw the needle quickly and place a drop of collodion over the point of puncture. In about 400 sternal punctures by this method there have been no complications, and in the

8. The concentration of this solution should be about 100 times the final concentration desired, so that only from 0.1 to 1 cc. need be added. A 1 cc. tuberculin syringe is used for accurately measuring these quantities.

of a 2 to 4 inch length of glass tubing of suitable size to fit a vaccine vial cap, stoppered at one end with such a cap, filled with nonabsorbent cotton and autoclaved. To obtain the filtered air, puncture the sterilized cap with a sterile needle and aspirate air through the cotton.

Conditions to Be Controlled.—If all vials in one set of experiments are treated exactly alike, that is, taken out of the incubator at the same time, centrifugated at the same time, and so on, one has a perfect control for the variable purposely introduced in the experiment. The p_H of the balanced salt solution should be between 7.4 and 7.8 and the p_H of the supernatant liquid removed at the time of changing mediums should not have fallen below 7.2.

Determining the Absolute Number of Each Cell Type Present.—By multiplying the percentage of a given cell type, as determined by a differential count of 500 nucleated cells,⁹ by the total nucleated cell count, the absolute number of that cell type in 1 c.mm. is determined. Multiplying this number by the total number of cubic millimeters in the vial gives the actual number of cells of each type present in the culture at any time.

The easiest way of finding mitotic figures⁹ is to cover the stained smear with oil and make a survey of the slide, using an 8 mm. objective and 10× eyepiece. When located by this method, they can readily be found under the oil immersion lens if one has previously determined the proper part of the 8 mm. field in which to place them. Locate a characteristic cell under the oil immersion objective, switch to the 8 mm. lens and note in what part of the field the cell lies. Always move a cell to this area before shifting to the oil immersion lens.

COMMENT

Among the noteworthy observations in the series of experiments on which this technic is based was the wide variation in conditions which marrow cells would tolerate. They survived any oxygen tension between 3 and 40 per cent and any carbon dioxide tension from that of air to 10 per cent. The oxygen and carbon dioxide tensions of air were fully as satisfactory as any other tested and more convenient to use. Cultures survived any p_H between 7 and 8 but seemed to do best at from 7.4 to 7.8. They would tolerate any osmotic pressure between that of 0.7 and of 1 per cent sodium chloride but did best in an isotonic or slightly hypotonic medium. They survived any temperature between just above freezing and 41 C., but the rate of multiplication and maturation is slowed down at the lower temperatures. They survive at room temperature for two weeks without a change of mediums. This permits shipping cultures, if protected from freezing, to any point in the United States. A surface to grow on is not essential, as has been thought to be the case for other tissues. Cultures have thrived at incubator temperature with continuous agitation for many days but there seemed to be no advantage to this.

Cultures appear to do quite well with a nucleated cell count as high as 14,000 per cubic millimeter but unless the medium is changed more often than once in forty-eight hours the counts will fall unless the total nucleated cell count is under 2,000 per cubic millimeter. It seems at first remarkable that the cells withstand centrifuga-

tion as well as they do, but they probably withstand more trauma in the circulating blood. It is possible to damage them by high speed, prolonged centrifugation, but even very frequent centrifugation at the speed recommended does not seem to damage them. It is further remarkable that no more débris of dead cells accumulates because, as will be shown,¹⁰ the duration of life of the mature neutrophil lobocyte (polymorphonuclear) is only about sixty to seventy hours, so that large numbers of them must die during the period of survival of these cultures. The débris is, however, phagocytized by the living cells and apparently reutilized. Dead and disintegrated red cells are similarly phagocytized.

The cells will also tolerate very wide variations in the composition of the medium. Since serum or plasma is one of the satisfactory ingredients, it is possible to study the differences in the effect of serum or plasma from any disease on the growth of marrow from any disease. We have already determined that the serum from untreated pernicious anemia patients lacks the factor necessary for reversion to the normal of the pernicious anemia marrow picture. This factor is present in normal serum, in serum from other diseases, and in potent preparations containing the antipernicious anemia principle. Therefore it should be possible to develop a quantitative test for antipernicious anemia principle as soon as a technic is developed of growing marrow in unlimited quantities and maintaining it in a state of deficiency of antipernicious anemia principle. No evidence has been obtained that serum of a person of the subject's blood group is any better than serum from a person of another group and the subject's own serum seemed inferior to cord serum. One would think that a medium consisting entirely of the subject's own serum or plasma would be ideal, but this results in rapid maturation. Since multiplication does not occur except in the lymphocyte and plasmacyte series, after maturation proceeds beyond a certain stage most of the cells in the cultures soon die. Lymphocytes even from blood cultures multiply indefinitely by amitotic division, but the normal lymphocyte has never been seen in mitosis.

Many ingredients have been tested for artificial or synthetic medium in a preliminary way. Some concentration of each of the following definitely seemed to favor growth: egg white, cerebrospinal fluid, cystein, peptone, concentrations of dextrose up to 0.5 per cent, thyroxine, vitamin C, hemin, pentose nucleotide, antipernicious anemia principle, and peptic digests of fibrin or egg white. Some concentrations of the following substances were found which seemed to favor growth and which certainly had no deleterious effect on the cultures: ferrous iron, copper, beef embryonic extract, chick embryonic extract, vitamins A, B and D, various amino acids and combinations of amino acids, insulin, theelin, glutathione, and anterior pituitary growth hormone. In all concentrations tried which had a detectable influence, the following ingredients had an apparently deleterious effect on the cultures: isotonic sea water, egg yolk, pig embryonic extract, amniotic fluid and tryptic digests. The most striking observation was the marked increase in mitosis (from forty to sixty times the number in the original marrow) produced by some as yet unidentified constituent of egg white, while chick embryonic extract, which has been so widely used in previous tissue culture

E., and Brownlee, Inez: *The Length of Life of the Neutrophils, Eosinophils and Basophils of Normal Blood as Determined by Comparative Cultures of Blood and Sternal Marrow from Healthy Persons*, to be read before the Section on Pathology and Physiology at the Eighty-Eighth Annual Session of the American Medical Association, Atlantic City, N. J., June 9.

work, was relatively much less effective. None of the statements made in this paragraph should be regarded as final, since they are based on relatively few experiments. A large series of carefully controlled experiments covering the whole range of variations in concentration of each ingredient from definitely inactive to definitely harmful will be necessary before its optimal concentration, mode of action and value as an ingredient of synthetic mediums can be reported. Probably a separate publication on each ingredient will be necessary. We have used the synthetic mediums of Baker¹¹ as our point of departure but many modifications have proved desirable and a great deal of work must yet be done before the ideal concentration of all ingredients will be known. These tentative results are reported because they may aid others who wish to work with the method.

Note that the method described employs no apparatus not present in a well equipped laboratory and no technic not known to a well trained technician and that it is suitable for quantitative experiments. We have cultured blood, spleen and lymph nodes by this method as well as marrow. It could undoubtedly be used for many other tissues. We have had living motile marrow cells at fifty days after removal from the human body and as long as six weeks after the death of the patient from whom the marrow was obtained. Undoubtedly cultures could be retained much longer if portions were not removed at such frequent intervals, thus eventually depleting the supply.

The methods and results to date will be shown in the Scientific Exhibit of the American Medical Association at Atlantic City, June 7-11.

Clinical Notes, Suggestions and New Instruments

A NEW RECORD IN LONGEVITY AFTER CORONARY THROMBOSIS

PAUL D. WHITE, M.D., BOSTON

S. R., a clergyman, died of congestive heart failure, Aug. 2, 1936, at the age of 73, in the twenty-fifth year after his first attack of coronary thrombosis. He was of a long-lived family, doubtless an important factor in the present consideration. He himself had always been in good health as a boy and young man, a strenuous worker and considerably overweight for many years. He had never had syphilis.

In May 1927 the patient consulted me for advice relative to a severe illness which he had suffered during evangelical meetings on Cape Cod two weeks before. While preaching, he had been suddenly seized by very severe epigastric and substernal oppression radiating strongly and equally to the two wrists, causing him to faint and lasting several hours, until relieved by two hypodermic injections of morphine. He had remained in bed one week, feeling well, except for some weakness and a short period of fever (up to 102 F.), which subsided after two or three days. On getting up and about he had noticed a little shortness of breath on exertion, but he had had no more pain.

It was then, in May 1927, at the time of my history taking in the case, that I discovered the remarkable fact that fifteen years earlier, in 1912, at the age of 48, he had the first of a series of four attacks, which were exactly alike except for severity, and which he and others had diagnosed "acute indigestion." The second attack occurred in 1915 at the age of 51, the third in 1923 at the age of 59, and the fourth, which was

the most severe of all, was the one which happened in 1927 at the age of 63, two weeks prior to his first visit to me.

On physical examination in May 1927 the patient was heavy and had normal breathing, fair color, normal reflexes, slight cardiac enlargement with diminished first sound at the apex but no murmurs and no evidence of congestive failure in the veins of the neck, the lungs, the liver, or the extremities. His pulse was regular at 78 and his blood pressure was 130 systolic and 80 diastolic. Electrocardiography showed normal rhythm, low voltage of QRS waves, inverted T waves in lead 1 and flat T waves in lead 2. He was put to bed for a few more weeks and advised to lose weight. Following these measures he improved rapidly and continued in good health for two years, at the end of which time paroxysmal angina pectoris developed for the first time; this was in 1929.

In 1931 he suffered his first attack of paroxysmal dyspnea with cardiac asthma; on digitalis he again improved greatly and his health was good during the next two years. He continued to preach and to do other ministerial work, but no longer under pressure. The winter of 1933-1934 he spent in Florida and returned north in fairly good condition, but at this time, at the age of 71, he retired from his work. He had reduced his weight in the course of several years from 222 to 178 pounds (101 Kg. to 81 Kg.). In May 1934 there occurred a paroxysm of tachycardia lasting three hours, but there were no more attacks of the sort thereafter. The next fall and winter he remained in good health but lived a very quiet life.

During the winter of 1935-1936 he was miserable in Florida, with much orthopnea at night. In May 1936 at the time of examination he looked very thin, his weight having fallen to 156½ pounds (71 Kg.). His heart was only moderately enlarged (by orthodiagram the transverse diameter of the heart was 13.9 cm. and the internal diameter of the thorax was 25.6 cm.), the sounds were fairly good, there were no murmurs, and there was no evidence of congestive failure. The blood pressure was 110 systolic and 70 diastolic. The electrocardiogram showed frequent ventricular premature beats, a heart rate of 80, sagging ST intervals in lead 1, moderate left axis deviation, and upright T waves in lead 4. I examined the patient for the last time on June 2 and found him improved; he had regained a few pounds and showed no congestion. He was on a daily ration of 1½ grains (0.1 Gm.) of digitalis. In Maine, where he spent his summers, he began about the middle of June to have increasing shortness of breath, especially at night, and he frequently required morphine for relief. The pulmonary congestion increased in degree up to the time of his death, August 2.

AUTOPSY

At autopsy the heart weighed 590 Gm. and there was moderate hypertrophy and considerable dilatation of the left ventricle, the wall of which showed extensive fibrotic changes with scarring in several different areas, particularly at the base of the left ventricle just under the endocardium and extending as far as the anterior papillary muscle, which was also considerably involved, and at the apex of the left ventricle, including also the anterior part of the interventricular septum. Over these areas, and in scattered points between, there was marked thickening with whitening of the endocardium and thinning of the ventricular wall. The greatest thinning was at the base posteriorly, where the wall was less than 5 mm. thick and showed slight aneurysmal outpouching. There was no intracardiac thrombus or evidence of pericarditis.

The right ventricle was hypertrophied to about twice its normal size, doubtless as the result of the several years of periodic insufficiency of the left ventricle with increase of pulmonary blood pressure. The muscle seemed in good condition macroscopically, and there was no evidence of fibrosis or scarring of the right ventricle. The auricles and valves were normal.

The coronary arteries were seriously affected and there was an astonishingly small blood supply possible through them. The right coronary artery, which was of unusually large size, had a very narrow lumen, nearly to the point of total occlusion in three places, two of which had apparently undergone recanalization. The right coronary artery was large and long and apparently normally supplied the posterior part of both ventricles. The left coronary artery was smaller than normal;

11. Baker, Lillian E.: Artificial Media for the Cultivation of Fibroblasts, Epithelial Cells and Monocytes, *Science* 53: 695-696 (June 19) 1936.

the circumflex branch was completely occluded by old calcification 1.5 cm. from its mouth, and the anterior descending branch showed considerable narrowing of the lumen. The coronary vessels throughout the heart felt like pipe stems. No fresh thrombus was found in them. The ascending aorta was smooth and the mouths of the coronary arteries were patent.

COMMENT

This case with postmortem proof of myocardial infarction establishes a new record in longevity after coronary thrombosis. The longest survival previously recorded was that of a patient who died in the eighteenth year after the acute infarction;¹ the patient who is the subject of the present report lived into his twenty-fifth year after his first heart attack and survived three other attacks of coronary thrombosis by twenty-one, thirteen and nine years respectively. It is likely that this record was made possible by the fact that not one of the infarcts was very large, that he belonged to a long-lived family, and that he reacted very well to treatment, consisting of digitalis and rest, when his myocardium did begin to fail. It seems quite certain that there are numerous other cases of very long survival but that they have not yet been confirmed post mortem.

SUMMARY

A new record in longevity after coronary thrombosis has been discovered in a man whose first myocardial infarction occurred at the age of 48, his second at 51, his third at 59 and his fourth at 63. He died of congestive heart failure at the age of 73, in the twenty-fifth year after his first coronary thrombosis. Postmortem examination revealed multiple areas of infarction in the left ventricle. In the previous record case survival occurred into the eighteenth year after one attack of coronary thrombosis.

Massachusetts General Hospital.

AN UNUSUAL COMPLICATION IN POTT'S DISEASE

ROBERT O. RITTER, M.D., CHICAGO

C. H., a boy, aged 11 years, first came under observation in the outpatient orthopedic department of St. Luke's Hospital in 1925. He had a marked kyphos, the result of tuberculosis of the sixth, seventh and eighth dorsal vertebrae. After several months' observation, the disease still being active, a spine fusion

operation was performed by the Hibbs method March 22, 1926. The first to the eleventh dorsal vertebrae, inclusive, were fused. There was nothing unusual about the convalescence, and after four months the patient left the hospital wearing a back brace with head support. Six weeks later he re-entered the hospital because of inability to control the legs. He was immobilized for three months on a Bradford frame without any improvement. November 23 the site of the original operation

Kyphos resulting from tuberculosis of the spine.

was explored with the expectation of finding a lack of fusion. On the contrary, there was a complete ankylosis. The cord was then exposed over the deformity by removing a wide strip through the middle of the fused area. A solid bony fusion remained on either side. An extradural abscess was found at the level of the sixth and seventh dorsal vertebrae. The dura was not opened. The wound healed readily but the spasticity

did not improve. In fact it increased, and the patient had all the neurologic signs of severe cord pressure. The thighs were flexed at right angles to the body and the legs at right angles to the thighs. No amount of effort could overcome these contractures.

It was not until August 1927 that the parents consented to another operation. The cord was exposed through the site of the former decompression. No extradural abscess was found, but the dura was tightly stretched over the sharp kyphos and its anteroposterior diameter was so narrowed that the cord was flattened like a ribbon. The dura was incised longitudinally. The cord, freed from pressure, bulged up through the opened dura. After all pressure was released, the wound was closed. Two weeks after this operation the patient could voluntarily move the toes of the right foot. Muscle control gradually returned and all spasticity disappeared. In three months he was up, pushing a wheelchair about the ward. He left the hospital Dec. 23, 1927, with full return of muscle control and no signs of cord pressure.

The boy then became a house-to-house canvasser, walking and climbing steps everywhere he went until May 2, 1931. On this date he fell down a flight of slippery steps, striking the kyphos at the edge of a step. He experienced a sudden severe pain, with an immediate loss of all muscle power and pain sense below the site of injury. He entered St. Luke's and the cord was exposed again by operation. It was found much swollen and congested over the kyphos. Longitudinal incisions were made into this area and the cord was found to be completely severed. The wound was closed and healing occurred promptly. However, he developed pressure sores over all bony prominences, and a severe cystitis. July 3 he was taken home, where he died a short time later.

122 South Michigan Avenue.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS. HOWARD A. CARTER, Secretary.

FASTEX SELF-ADHERING GAUZE NOT ACCEPTABLE

Manufacturer: The Fastex Corporation, 730 McKnight Building, Minneapolis.

Fastex is recommended by the manufacturer for bandaging wounds, sprains, strains and other injuries when protection is needed. The gauze is self adhering, requiring no adhesive tape, no pins, no strings or tying to make it stay. According to the manufacturer it is not affected by water and does not stick to the hair or skin. It is claimed to be porous, permitting the passage of air to the wound or injury. It is indicated, according to the manufacturer, for first aid, minor emergency use and certain types of operative work in which a self-adhering gauze would prove more advisable; viz., an idiosyncrasy to adhesive tape or a tape rash.

In the production of Fastex Self-Adhering Gauze, the firm claims that bleached, sterile gauze (44 by 40) is used. The gauze is coated with a neutral rubber composition containing resins. During the process the coated material is immersed in a solution containing metaphen and eosin and further subjected to a temperature of 212 F. The firm claims that this resultant gauze is sterile and that it may be placed on an open wound in the same manner as ordinary sterile gauze but has the advantage of being self adhesive and as such more convenient to use. It is recommended by the manufacturer in instances in which physicians prescribe adhesive tape to overcome thumb sucking in babies and children.

The firm was requested to supply information concerning the possible contamination of the latex during the process of manufacture, the length of time the latex is held at 212 F., and whether or not the box in which the roll is placed was sterilized. The firm replied that the latex is held at 212 F. for approximately twelve minutes and that this heat treatment is primarily a step in the manufacturing process and only incidentally considered a sterilization measure. The firm fur-

1. White, P. D.: Longevity After Coronary Thrombosis, J. A. M. A. 100: 233 (Jan. 29) 1933.

ther stated: "Both the heat degree and the length of time in which material is subjected to that probably is not to be considered sufficient. The latex, during the manufacturing process, is not subjected to contamination except as it is momentarily exposed to the air in passing through the process."

The manufacturer claims that its products are subjected to standard autoclave treatment after being wrapped. Pressure cooker equipment, which gives bone-dry sterilization under 20 pounds of pressure for thirty minutes, is employed.

The Fastex Self-Adhering Gauze, as supplied to the trade, was referred to a clinic acceptable to the Council for investigation and report. The Council's investigator employed the methods and technic customarily used in bacteriologic examinations. He reported that bacterial growth occurred in the majority of tubes inoculated with the gauze under consideration, and that at least four different species of bacteria were encountered. No identification was attempted, but the predominant species appeared to be *B. subtilis*.

Control tubes opened in the same manner as the test tubes, but not inoculated, showed no growth.

A control series of tubes in which autoclaved gauze was cultured showed no growth. Subsequent growth after inoculation of three species into these tubes indicates that the absence of growth was not due to a growth-inhibitory substance which might have dissolved out of the gauze.

The Council's investigator concluded that bacteria were present in the gauze as furnished him.

The Council on Physical Therapy voted that Fastex Self-Adhering Gauze be declared not acceptable for inclusion in its list of accepted devices because the product was not sterile as claimed but was found to be contaminated with bacteria.

HANOVIA HOME MODEL ALPINE SUNLAMP (Models S-309 and E-302) NOT ACCEPTABLE

Manufacturer: Hanovia Chemical and Manufacturing Company, Newark, N. J.

The Hanovia Alpine Sunlamp (Models S-309 for alternating current and E-302 for direct current) is recommended by the firm, for home use. It is an improved model of the Hanovia Home Model Alpine Sunlamp, which was accepted by the Council (*THE JOURNAL*, Oct. 20, 1934, p. 1229). Solid activated electrodes are used now because, according to the company, the danger of breakage in shipment is reduced, and the lamp lights on turning the switch without the necessity of tilting the burner. Otherwise the firm claims the characteristics of Models S-309 and E-302 are the same as the previously accepted model.

The lamp gives the typical high pressure hot quartz mercury arc spectrum, and the spectral energy distribution is almost identical with that of all other high pressure hot quartz mercury arc lamps.

The intensity of the lamp is from 180 to 200 mw/cm² for radiations 3,130 angstroms and shorter, and from 320 to 360 mw/cm² for the total ultraviolet, when measured directly opposite the burner with the burner mounted in its reflector and 30 inches distant. Under the same conditions at 36 inches, the intensity is from 125 to 140 mw/cm² and from 250 to 270 mw/cm² respectively.

At 40 inches the intensity of radiations 3,130 angstroms and shorter is 90 mw/cm², being about the same as the intensity for summer sunshine at Washington, D. C., for the sun's radiations 3,130 and shorter.

The life of a burner is from 1,500 to 2,000 hours, the depreciation being mainly the blackening of the walls of the burner.

It is to be remembered that the Council accepts for home use only lamps that emit practically no ultraviolet radiation of wavelengths shorter than 2,800 angstrom units. The Home Model Alpine Sun Lamp (Models S-309 and E-302) emits such radiations, but this might be eliminated if a corex window was used.

With regard to the time of exposure to produce an erythema, the firm states that for the average individual a first exposure

should be made at 30 inches and for not longer than four minutes on any one body surface.

The advertising matter was examined and was found to be unacceptable. The leaflet "Announcing the New Hanovia Alpine Sun Lamp for Your Home" contains, among others, statements such as: ". . . will help you keep fit and build your resistance against disease"; "Its beneficial ultraviolet rays will not alone increase your energy but they quiet your nerves, stimulate your appetite, and induce sound and restful sleep"; ". . . whose cool, beneficial rays are the most effective means for maintaining the health of children and building up their resistance to diseases and ailments"; "The wavelength distribution of the rays emitted from this new burner resembles very closely that of the sunshine high up in the mountains at the elevations where the most beneficial ultraviolet rays have not yet been filtered out by dust, smoke or other absorbent elements. Sunshine of such beneficial quality can never be enjoyed at sea level or below about 5,000 feet, not even on very clear days with bright sunshine"; "Brings the mountain sun into your home."

As the Hanovia Chemical and Manufacturing Company has not submitted critical evidence to substantiate the aforementioned claims, the Council declared the lamp nonacceptable.

When the foregoing report was submitted to the Hanovia Chemical and Manufacturing Company, a suggestion was made that the lamp be equipped with a filter to remove the ultraviolet radiation of wavelengths shorter than 2,800 angstroms. In its reply the company rejected the suggestion to so equip the sunlamp, giving as its reason that such filters do not exhibit a sharp cut-off at 2,800 angstroms, transmitting all longer rays and absorbing all shorter rays. Instead the firm states that filters do absorb an important part of the rays of 2,900 and 3,000 angstroms.

The firm further stated that it most emphatically denied on a basis of the present day evidence that ultraviolet in such quantities as are likely to be used in the home might cause deleterious changes in the skin and that such evidence existing refers to cases exposed to natural sunlight. Excerpts from articles written by several specialists in ultraviolet therapy were cited to support the firm's contention. The purpose of these excerpts, according to the firm, emphasize the point that "ultraviolet will help to maintain health as near to par as other circumstances permit."

The Council observed that the excerpts were taken from articles prepared by specialists on the subject of ultraviolet radiation. Articles from which excerpts are taken may have an entirely different meaning when considered as a whole, but an excerpt viewed along with or in the presence of thoughts of another nature may be misleading.

The objection raised by the firm to compliance with the requirements to furnish a Corex D filter did not seem insurmountable to the Council. A single thickness of Corex D glass transmits 10 per cent ultraviolet radiation at 2,804 angstroms, 50 per cent at 2,967 angstroms and 75 per cent at 3,132 angstroms. This is the spectral region which has been recognized as efficacious for prophylaxis in rickets. According to the records submitted by the firm, at 30 inches the sunlamp in question produces an erythema in about four minutes. This time is entirely too short for sunlamps used in the home without the supervision of a physician. The Council pointed out, however, that the lamp met the specifications of the Council for acceptance, provided it was used under the supervision of a physician.

In the opinion of the Council and its consultants, the information presented by the firm was insufficiently conclusive to warrant a change in action.

In view of the foregoing, the Council voted to reaffirm its stand that the Hanovia Home Model Alpine Sunlamp (Models S-309 and E-302), be declared unacceptable for inclusion in its list of accepted devices because: (1) when the lamp is used without the Corex D window the ultraviolet of wavelengths shorter than 2,800 angstroms is greatly in excess of the value acceptable to the Council for sunlamps recommended for home use, and (2) because the lamp is recommended for use without the supervision of a physician.

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS.
PAUL NICHOLAS LEECH, Secretary.

"CICAL BASE 125" NOT ACCEPTABLE FOR N. N. R.

Under the name "Cical Base 125," Chemical Industries of California requested the Council's consideration of an ointment base stated to be composed of stearic acid, spermaceti, white wax, terpineol, an especially processed stable animal oil, distilled water, triethanolamine and sodium benzoate. The firm claims the use of this ointment base to be "of value in dry skin, senile skin, sunburn, windburn and ichthoid conditions." In addition it is proposed as an ointment base for prescriptions. As such it is claimed to be superior to those in common use because diffusible in the presence of serous and sanguineous exudates.

At the time of presentation of the product, the firm was asked for information (1) as to the purity of the triethanolamine, (2) as to the nature of the "especially processed, stable animal oil" and (3) as to the justification for the use of a proprietary noninformative name involving the use of numbers. The firm replied that the triethanolamine used consists of approximately 82½ per cent triethanolamine, 15 per cent diethanolamine and 2½ per cent monoethanolamine. Concerning the oil used in the product, the firm states "There are patents pending on the especially processed stable animal oil used in CICAL BASE 125. It will depend entirely on the type of patents granted whether we shall be able to divulge the formula . . ." The firm indicated that, if the patents were issued, the formula would be supplied to dermatologists already using the product so that they may be able to report on its clinical use. At present, therefore, the product is essentially a secret one. The firm has not supplied adequate methods for determination of the identity and purity of the product. In this connection the firm states that the constituents of the various ingredients are related and chiefly inert and fatty in nature, making accurate identification and assay of the stearic acid, spermaceti, white wax, terpineol and the "stable animal oil" impossible because on mixing, the identifying characteristics are lost. The Council could not, of course, accept a product on the basis of the inadequate statement of identity and composition now available.

Concerning the name "Cical Base 125" the firm stated that it is willing to make necessary changes in case the Council finds the name in conflict with its rule. The firm proposed exemption of the product from the Council's rule concerning the use of numbers and letters in names on the ground that this was a special case in which the use of a numeral or letter seems desirable because further improvement of the product was anticipated. As alternative for a numbered series, the firm proposed the use of such names as Cical Base Hydrous, Cical Base Anhydrous, Cical Base Heavy, Cical Base Medium and Cical Base Light. The name as it stands is in obvious conflict with the Council's rules. In the first place there is the objectionable secrecy in connection with the "processed stable animal oil." The name "Cical" is essentially meaningless. Sufficient proof of the originality of the product has not been furnished to justify exemption of the product from the rule concerning the use of numbers in names. The alternative names proposed by the firm are not considered satisfactory.

The Council considered advertising submitted by the firm consisting of a leaflet entitled "Cical Base 125-Diffusible in Exudates," a booklet "Chemical Industries of California-Cical," a price list, on the back of which appears the names of various Cical products with a statement of indications for each, and a printed sheet detailing four case histories.

In the advertising the following list of Cical products are mentioned: Cical Base 125; Salbencal (Whitfield); Salbencal Half Strength; Carsincal; Sulpercal; Sulpercal Half Strength; Ammercal No. 1; Ammercal No. 3; Ammercal No. 5; Cical Lotion; Cical Lotion With Oil; Tarcical; Cical Pomade; For-

mical (Lotion); Cical Pine Tar Shampoo and Veracal. None of these have been presented for the Council's consideration and no proof for the claims made for any of them has been submitted.

Concerning Cical Base 125, such claims as the following are made in the advertising: "Remarkable in softening and emollient properties, CICAL BASE 125 possesses that desirable power of penetration inherent in animal oils, fats and waxes." "Because of its complete diffusibility, it offers a maximum dosage of medicaments incorporated in it to the area under treatment." "CICAL BASE 125 is entirely lacking in the clinging greasiness so characteristic of petrolatum (vaseline) bases and has none of the disagreeable odor or stickiness of lanolin (wool fat)." It is stated to be very stable with no tendency to turn rancid on aging. The broad claim is made that Cical Base 125 has advantages possessed by no other base. The only proof submitted for this broad claim is two photomicrographs in the circular "Cical Base 125-Diffusible in Exudates," purporting to show the difference in diffusibility of hydrous lanolin in contact with a drop of water and Cical Base in contact with a drop of water. This is certainly not proof for such broad claims as the firm advances. The case histories presented show nothing unusual or extraordinary and certainly cannot be considered as competent controlled clinical evidence to establish the therapeutic claims made for Cical Base 125.

The Council declared "Cical Base 125" unacceptable for inclusion in New and Nonofficial Remedies because it is a preparation of essentially secret and uncontrolled composition marketed under a proprietary, noninformative name (in which there is the use of numbers), with unsupported therapeutic claims.

When the foregoing report was sent to the firm, it replied at length giving its reasons for presenting the product for consideration, explanation for its claim concerning the diffusibility of the base, explanation of the significance of the names (the name Cical, for instance, being derived from the initials of the firm name, Chemical Industries of California) and a résumé of its marketing policies. None of this in the opinion of the Council furnished reason for modifying the report of the Council's consideration. The Council therefore reaffirmed its rejection and authorized publication of the statement.

ANTICOMAN NOT ACCEPTABLE FOR N. N. R.

Anticomman tablets were submitted to the Council on Pharmacy and Chemistry by Bruno L. Monias, American representative of Anticomman G.m.b.H. of Berlin-Halensee, Germany, as a therapeutic agent for the correction of hyperglycemia and glycosuria. The tablets are said to consist of pancreatic enzymes, sodium phosphate, tannic acid, bismuth subnitrate and decamethylenediguanidine ditartrate. A previous Council Report held another product (Pancresal), proposed for the same purposes, to be unacceptable (THE JOURNAL, May 27, 1933, p. 1686) which contained, similarly, a guanidine derivative together with a number of other substances.

For the purpose of correcting hyperglycemia it may safely be said that (1) tannic acid, bismuth subnitrate and sodium phosphate are worthless and (2) that no pancreatic extract on oral administration has been shown thus far to have any effect.

Since the employment in 1926 of decamethylenediguanidine under the name of Synthalin by a number of workers (notably Frank, Nothmann and Wagner) in the treatment of diabetes, a rather extensive literature has accumulated. Apparently the drug does produce a reduction in blood sugar but, as shown by Morawitz and verified by Hornung, and by Boedeker and Junkersdorf (Solmann, Torald: A Manual of Pharmacology, ed. 4. Philadelphia, W. B. Saunders Company, 1936) this action is quite different in mechanism from that of insulin. Here the hypoglycemic influence is accomplished through damage to liver function and structure leading to exhaustion of hepatic glycogen. The therapeutic effect of the drug is shown by Bischoff to parallel closely the degree of toxicity and extent of liver damage produced. Other workers have reported the consistent side-effects of severe gastro-intestinal disturbances, nervous depression and even acute nephritis.

In view of the danger attending the use of guanidine derivatives, as contrasted with the singular freedom from toxicity accompanying the intelligent administration of insulin, it would seem to constitute a lack of therapeutic finesse to employ the former, regardless of the lesser convenience occasioned by the parenteral route.

Anticomman presents other features which are in conflict with the rules of the Council, but the most important from the standpoint of physician and patient alike is that such mixtures tend to replace a thoroughly investigated and highly satisfactory drug (insulin) with one of dubious and unpredictable therapeutic value which presents significant toxicologic possibilities.

Until there is clear cut, carefully controlled evidence, no product which is in the twilight zone of this field of scientific experimentation should be employed for the treatment of diabetes, for which the physician already has in his armamentarium the excellent insulin and the helpful dietary regimen.

The Council declared Anticomman not acceptable for New and Nonofficial Remedies because it is a mixture of well known substances marketed under a therapeutically suggestive name with unwarranted therapeutic claims which may tend to replace the use of a scientifically correct and physiologically sound therapeutic regimen.

This report was submitted to the manufacturers, and the reply indicated that the firm felt that Anticomman was being discriminated against. The Council gave it the same attention, consideration and evaluation that any other product receives. The firm claimed that the guanidine content was detoxified by the pancreatic powder; but while there is some evidence that Anticomman does not produce the degree of damage encountered with other guanidine compounds, evidence that such effects were never encountered has not been submitted to the Council. The firm stated that it was open to suggestion as to a name. The Council replied that it would consider the question of a name provided the other objections were met. The firm asked for reconsideration of the usefulness of Anticomman in cases of mild diabetes with and without insulin. Such reconsideration led the Council to recommend that the previous action be reaffirmed and the report be approved for publication.

The firm was notified of this action and in reply reiterated certain points which it has attempted to maintain without submitting what the Council considers adequate evidence to support the contentions involved. The whole question was reviewed by the Council and the previous action reaffirmed.

POISONIVI AND POISONOK NOT ACCEPTABLE FOR N. N. R.

A physician called the attention of the Council to a letter sent by the Cutter Laboratories to one of his patients recommending "Poisonivi" to be taken by mouth. Some products of this firm stand accepted by the Council and the firm should therefore be familiar with the Council's rulings. Although the Council has accepted some rhus preparations marketed under correctly informative names, it has not accepted, nor previously considered, the preparations Poisonivi and Poisonok of the Cutter Laboratories, which are proposed for use against rhus poisoning and are marketed under coined, therapeutically suggestive names. The Secretary asked the firm whether the physician had been correctly informed that this product was being directly advertised to the public. In reply to the Secretary's inquiry, the firm wrote (Oct. 7, 1936):

"For some years we have marketed 'Poisonivi' and its companion product 'Poisonok' through drug channels, although this has been confined almost exclusively to the West Coast.

"Occasionally here in the East we receive mail inquiries from people who have either used the material successfully in the past and wish to obtain more of it, or from people who have heard of the product from others, who have used it and ask us for information about it.

"When such inquiries received their reply from us, the products and its limitations have been described and the enclosed circular is attached to our reply.

"We are not aware that we have trespassed any rules in sending out this sort of information in response to inquiries on this product, which, by the way, is the only one we manufacture which is handled in this manner. I would appreciate hearing from you further if we are wrong in this case."

The Council considered the circular sent by the Cutter Laboratories and found that it could not be held as anything but

indirect advertising to the public of medicinal preparations, a direct contravention of the Council's rules. In the circular under consideration the products are advertised as curative agents. Moreover, the lay advertising of these preparations will undoubtedly tend to promote self medication very harmful in character. It is almost superfluous to point out the danger which might arise from the lay person's diagnosing his condition and treating it with a preparation which might not be intended for his real affliction and which indeed might aggravate it. If Poisonivi and Poisonok have any merits they may much better be directed to the medical profession.

The Council declared Poisonivi and Poisonok unacceptable for New and Nonofficial Remedies because they are marketed under proprietary, therapeutically suggestive names and advertised directly to the public.

ENDO-BISARPHEN NOT ACCEPTABLE FOR N. N. R.

Endo-Bisarphen is the proprietary name under which Endo Products, Inc., markets a product stated to be "... a combination of organic arsenic with bismuth, in solution eminently suitable in 'Wassermann-fast' cases and in congenital syphilis." In an advertising circular it is stated that "Each 2 cc. represents approximately 26 mgm. of metallic bismuth combined with 10 mgm. of Arsenic in the form of a Paraglycolamino-arsenic acid derivative, of the Arsphenamine type."

Endo Products, Inc., has not submitted this preparation for the Council's consideration, nor has any product of this firm been considered or accepted by the Council. The A. M. A. Chemical Laboratory has made no investigation of the preparation, and no actual chemical analysis of the product is available.

An advertising circular bearing the caption "Endo Bisarphen, Bismuth & Arsenic combined in a stabilized solution for Intramuscular Administration in all stages of Syphilis" contains the following statement: "It is a generally accepted theory that Arsphenamines become spirocheticidally active only after they have been converted into a chemical substance which is therapeutically effective. Bisarphen, however, is directly spirocheticidal and undergoes no chemical changes, permitting for its immediate action." No proof for this claim is given. There are five brief and wholly inadequate "case histories" furnished in this circular. All refer to so-called Wassermann-fast cases and are worthless from the standpoint of showing the value of Endo-Bisarphen.

The only literature that can be found on Endo-Bisarphen is a favorable but inadequate paper by Dr. Jacob Skeer (*Urol. & Cutan. Rev.* 37:495 [July] 1933). He stated that he had given about 700 injections of the product intramuscularly. The number of cases treated was not stated, nor were the types of cases outlined. The product, he states, was devised by Vincent Christina in 1929 and is claimed to be a combination of bismuth and arsenic, a synthetic compound, each 2 cc. ampule containing 44 per cent metallic bismuth and 16 per cent organic arsenic. The author claims that it has a higher water soluble bismuth content and a higher arsenic content than any other compound. He makes the statement "According to findings of syphilologists ultimate effects are equal to that of modern intensive combined treatment with arsphenamine, bismuth and mercury." He states that the spirochetes have been known to disappear in forty-eight hours and that lesions are healed after ten to twenty injections.

The author also states that it is of value in relieving gastric symptoms and the lightning pains of tabes and in Wassermann-fast cases. Since he has given only 700 injections of the product himself, and there is no literature to call on, it is difficult to see how the ultimate effects of the product, "according to findings of syphilologists," could be "equal to that of modern intensive combined treatment with arsphenamine, bismuth and mercury."

No information is available as to the real effect of Endo-Bisarphen on the disappearance of spirochetes from primary lesions, the rapidity of disappearance of secondary lesions, or the true effect on cerebrospinal syphilis from the standpoint of study of clinical results, change in cell count or change in

serologic reactions, in gold colloid curve, and so on. No real evidence of either the efficacy or toxicity of this product has ever been cited.

The firm apparently is a subsidiary of the Intravenous Products Company of America, Inc., 251 Fourth Avenue, New York City. No preparation of either of these organizations stands accepted by the Council for inclusion in New and Non-official Remedies. A note appeared in THE JOURNAL fifteen years ago ("Intravenous Specialties," THE JOURNAL, Dec. 10, 1921, p. 1912) concerning certain preparations of the Intravenous Products Company of America. The present day advertising of both the Endo Products Co. and the Intravenous Products Company of America Inc. leaves much to be desired, particularly from the standpoint of scientific accuracy.

The physician should contrast the method of introduction of Endo-Bisarphen with that of another firm which has recently introduced an arsenical for the treatment of syphilis. The latter firm conducted researches over a period of three years, spent large sums of money and had the advantage of study of many hundreds of cases in several university clinics in this country before it deemed the product ready for submission to the Council, and only after the product was accepted by the Council did the firm venture to put it on the market for general use in the treatment of syphilis. Apparently, the promoters of Endo-Bisarphen have chosen to market their preparation without the benefits afforded by time-consuming but essential preliminary procedures of this sort.

The Council declared Endo-Bisarphen unacceptable for inclusion in New and Nonofficial Remedies because it is a preparation of inadequately declared composition and unsubstantiated therapeutic usefulness, marketed under a proprietary name with unwarranted therapeutic claims.

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary.

SYNTROPAN.—The phosphate of *d*-1-tropic acid ester of 3-diethylamino-2,2-dimethyl-1-propanol — $C_6H_5.CH(CH_2OH)COO.CH_2C(CH_3)_2CH.N(C_2H_5)_2.H_2PO_4$.

Actions and Uses.—The actions of syntropan are similar to those of atropine. However, syntropan acts to a certain extent directly on smooth muscle in addition to its inhibitory effect on parasympathetic endings. It does not depress salivary secretion as actively as atropine or induce mydriasis as readily, and its inhibitory action on the parasympathetic innervation of the heart is not as pronounced as that of atropine. Syntropan is employed for its antispasmodic action on smooth muscle.

Dosage.—For oral administration, one tablet (50 mg.) three or four times a day; for subcutaneous or intramuscular administration, 1 cc. of syntropan solution (representing 10 mg. of syntropan) three times a day.

Manufactured by Hoffmann-LaRoche, Inc., Nutley, N. J. U. S. patents 1,932,341 (Oct. 24, 1933; expires 1950) and 1,987,546 (Jan. 8, 1935; expires 1952). U. S. trademark 308,080.

Ampuls Syntropan Solution, 0.01 Gm., 1 cc.

Tablets Syntropan, 0.05 Gm.

Syntropan occurs as a white, crystalline powder, with a faint roseate odor and having a bitter taste; freely soluble in water, slightly soluble in absolute alcohol, insoluble in chloroform and ether. The aqueous solution is acid to litmus. Syntropan melts at 142 to 145 C. From aqueous solutions, alkali hydroxides precipitate the free base as a water-white oil, which does not solidify at ordinary temperature.

Place about 0.01 Gm. of syntropan in a porcelain dish, add a few drops of nitric acid, and evaporate to dryness on a water bath; a yellow residue results; cool, add a few drops of alcoholic potassium hydroxide solution; the mixture is a violet color.

Dry about 0.5 Gm. of syntropan, accurately weighed, to constant weight at 100 C.; the loss in weight does not exceed 1 per cent. Incinerate about 0.5 Gm. of syntropan, accurately weighed, in a platinum crucible; the residue does not exceed 0.1 per cent. Transfer about 0.5 Gm. of syntropan to a 500 cc. Kjeldahl flask and determine the nitrogen content according to the official method described in Official and Tentative Methods of Analysis of the Association of Official Agricultural Chemists, third edition, page 20, chapter 2, paragraph 22; the percentage of nitrogen corresponds to not less than 3.3 per cent nor more than 3.6 per cent when calculated to the dried substance.

Council on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COUNCIL ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION AND WILL BE LISTED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED.

FRANKLIN C. BING, Secretary.

COLONIAL FLOUR, PHOSPHATE ADDED

Manufacturer.—Bliss Milling Company, Seymour, Ind.

Description.—An "all purpose" "short patent" flour milled from soft wheat with 0.4 per cent added monocalcium phosphate; bleached.

Manufacture.—Selected soft Indiana wheat is cleaned, scoured, tempered and milled by essentially the same procedures as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended and bleached with a mixture of benzoyl peroxide and calcium phosphate ($\frac{1}{4}$ ounce per 196 pounds) and with nitrogen trichloride ($\frac{1}{4}$ ounce per 196 pounds) and with 0.4 per cent monocalcium phosphate.

Analysis (submitted by manufacturer).—Moisture 12.2%, total solids 87.8%, ash 0.7%, fat 0.7%, protein ($N \times 5.7$) 8.4%, crude fiber 0.3%, carbohydrates other than crude fiber (by difference) 77.7%.

Calories.—3.50 per gram; 99 per ounce.

MAYBELLE BRAND OLEOMARGARINE

Manufacturer.—The Cudahy Packing Company, Chicago.

Description.—An oleomargarine prepared from hydrogenated oleo and cottonseed oils, pasteurized cultured skimmed milk and salt. It contains 0.1 per cent of sodium benzoate.

Manufacture.—Hydrogenated oleo and cottonseed oils are heated in a steam-jacketed kettle, emulsified with the added milk and salt, and crystallized. The mixture is churned until the proper consistency is obtained, refrigerated, molded into prints and automatically wrapped and packed in cartons.

Analysis (submitted by manufacturer).—Moisture 15.4%, total solids 84.6%, ash 3.32%, sodium chloride (NaCl) 3.25%, protein ($N \times 6.25$) 0.3%, fat (ether extract) 80.3%, carbohydrates (by difference) 0.7%.

Calories.—7.27 per gram; 206 per ounce.

(1) PERFECT'S BRAND GOLDEN TABLE SYRUP

(2) PERFECT'S BRAND CRYSTAL WHITE TABLE SYRUP

Distributor.—A. H. Perfect and Company, Fort Wayne, Ind.

Packer.—Torbit and Castleman Company, Louisville, Ky.

Description.—Table syrups; (1) a blend of corn syrup (90 per cent) and refiners' syrup (10 per cent); (2) a blend of corn syrup (90 per cent) and sucrose syrup (10 per cent) flavored with vanilla; the same as Bob White Brand Fancy Golden and Crystal White Table Syrups (THE JOURNAL, Aug. 3, 1935, p. 369, and Oct. 19, 1935, p. 1271).

KING OF HAWAIIA BRAND PINEAPPLE DESSERT CUTS

Distributor.—Alexander & Baldwin, Ltd., Honolulu, Hawaii.

Packers.—Kauai Pineapple Company, Kalahoe, Kauai; Baldwin Packers, Ltd., Lahaina, Maui, and the Maui Pineapple Company, Kahului, Maui (subsidiaries).

Description.—Essentially the same as crushed, sliced and tidbit pineapple products distributed by Alexander and Baldwin (THE JOURNAL, April 13, 1935, p. 1331, and June 8, 1935, p. 2097) except for the shape of the pieces. All trace of the core and fiber is removed from the fruit.

SATURDAY, MAY 22, 1937

THE RABIES MENACE

The alarming situation which prevailed throughout the country last year in relation to dog-bites and rabies appears even more menacing this spring. During the recent warm days, according to newspaper reports, more than a hundred persons have been bitten by dogs daily in the city of Chicago alone. This represents more than a 50 per cent increase over the number of bites during the similar period of 1936. More heads of suspected animals have been examined, and the number found positive for rabies has also increased more than 50 per cent. A dramatic illustration of the situation was provided by a mongrel, believed rabid, which invaded an elementary school classroom in Chicago two weeks ago and bit four pupils. Two more children were bitten before this rabid animal was captured. Similar incidents seem inevitable as long as the numerous stray dogs remain at large.

Although conditions in Chicago may be more serious than those elsewhere, the situation is also actually or potentially critical in all other districts where dogs, especially strays, are numerous. The problem has received previous recognition in *THE JOURNAL*.¹ As judged from reports from all over the world, rabies is generally far from quiescent. The Sixth Analytical Review² on the Results of Anti-Rabies Treatment published by the League of Nations may be cited. The statistics quoted refer almost entirely to the year 1933, which in general may be considered far less dangerous than now. The mortality figures are based on reports from Pasteur institutes and hence cover only treated cases. The mortality among 286,373 Europeans was 0.16 per cent, and in the case of 219,681 non-Europeans the mortality rate was 0.72 per cent. These were the combined figures available. Another significant point mentioned in the review was that twelve out of 2,500 persons bitten on the limbs and beginning treatment within a week developed rabies, and each of the twelve

developed rabies within thirty days after having been bitten. The need for constant vigilance in starting treatment early is clearly indicated.

The extent to which informed sources recognize the great danger of rabies is further illustrated by the fact that the Rockefeller Foundation began a program of laboratory and field work on rabies in 1936. This disease, according to the foundation report,³ has become increasingly menacing, particularly in some of the Southern states. With this recognition that some regions are more threatened than others, it must also be emphasized that no areas where possible carriers of rabies are present can be considered exempt. The Rockefeller report also states that there has been little research on this disease since Pasteur's time. A quicker and more positive test for rabies in animals and a less cumbersome method of vaccination are badly needed.

All these facts point to the conclusion that immediate and coordinated action is necessary. Rabies is a disease in which individual efforts are relatively helpless unless aided by the full machinery of social organization. The press, public health officials, the police and physicians—in both their individual and their official capacities—should take steps to combat this threatening situation at once if a considerable number of unnecessary deaths is to be avoided. In the face of the now existing information as to the frequency and rapid spread of rabies among animals, it seems criminal to postpone action until the disease is identified in human beings. Because rabies is primarily a disease of dogs, it seems likely that this campaign will have the whole-hearted support of all the animal humane societies.

REPRODUCTIVE PERFORMANCE IN MAN

The purpose of a recently reported study by Pearl¹ was to determine the proportion of women potentially capable physiologically of reproducing in 1930 who actually did so in that year. In the birth registration area of the United States, which in 1930 included all the states except Texas and South Dakota, there were 30,871,292 living females between the ages of 15 and 50. Approximately 63 per cent were married, while 37 per cent were either single, widowed or divorced. Nevertheless, as Pearl points out, the vast majority of them were potentially capable physiologically of reproduction. Theoretically, therefore, there might conceivably have been an equal number of births, or at least some kind of product of conception during that year. Actually, in 1930 there were officially recorded as occurring in the same area to mothers aged 15 to 49 inclusive a total of 2,256,913 living and stillbirths, including the illegitimate as well as the legitimate. This does not represent all the reproductive activity of the year, since it does not include a considerable number of

1. Pearl, Raymond: Potential and Actual Reproductive Performance in Man, Human Biol. 8:592 (Dec.) 1936.

unrecorded abortions, nor does it record, on the contrary, the inclusion in the total of multiple births, each of which required only one mother. After correction Pearl takes the approximate figure of 2,287,196 births probably produced by mothers between 15 and 49 years of age inclusive in 1930. Thus only about 7.4 per cent of the females physiologically potentially capable theoretically of reproducing in that year actually did so. Even if 15 per cent is deducted because of probable physiologic sterility, the percentage of births to physiologically eligible women rises only to 8.7. It follows that if each of the women from 15 to 49 years of age was to reproduce annually for approximately thirty-three years at the average rate exhibited by the whole group in 1930 she would produce as an average in her whole reproductive life a total of approximately 3.3 births. This figure is startling in its contrast to the conditions which prevail among organisms lower in the evolutionary scale than man. Individually and racially there appears to be, under the present social and environmental conditions, a slow but definitely progressive trend toward less and less human reproduction without any material lessening of human sexual activity. Thus it seems probable that while only about 10 per cent of the women theoretically potentially capable of reproduction in 1930 actually reproduced, at least 70 to 75 per cent of them were sexually active in greater or lesser degree in that year.

More than three fourths of all the births in 1930 were to native white mothers. Also, more than three fourths of all the women who potentially might have been mothers were native whites. Of the remaining births, 11.5 per cent were to colored mothers, of whom probably over 92 per cent were Negroes. Taken as a whole, the closeness of agreement in 1930 between the percentages of live births and of potential mothers by nativity-race classes was extraordinary. Each nativity-race class, whether native white, foreign-born white, Negro or other, was, as a whole group, reproducing in 1930 proportionately to its representation in the population with a near approach to exact precision. Any idea that foreign-born women as a group in the whole United States population are at the present time outbreeding their native-born sisters—a notion of rather widespread journalistic prevalence, at least—finds no vestige of support from the actual facts of 1930.

Under present environmental conditions, Pearl says, and especially under the present social and economic environment, there seems to be evidence of a slow progressive trend toward more facultative interference with reproductive activity. If such a trend should persist indefinitely, man would eventually disappear, and while this prediction has been made it seems unlikely of fulfillment. The bulk of reproducing in all nativity-races is done by women between the ages of 20 and 34 years. Since this is true for all groups, and, as has been previously mentioned, their weighted mean relative fertilities, on a live birth basis, were, for each of the

groups as a whole, approximately equal, and since, as has been also determined, the contraceptive efforts of Negroes are both less frequent and less effective, interpretation of the facts offers considerable difficulty. Pearl concludes that a really sound judgment as to the precise nature and degree of the effect of contraceptive practices on the overt or expressed reproductivity of large population aggregates is still a long way from being understood.

SYMPOSIUM ON HEALTH PROBLEMS IN EDUCATION AT ATLANTIC CITY SESSION

For the first time at a meeting of the American Medical Association a program¹ will be presented by the Joint Committee on Health Problems in Education, through which the American Medical Association has cooperated with the National Education Association since 1911. The American Medical Association Sections on Pediatrics and on Industrial and Preventive Medicine and Public Health have joined in sponsoring this symposium. The National Education Association, representing more than 200,000 teachers, and the American Medical Association, representing more than 100,000 physicians, are the natural and logical groups to cooperate in the solution of health problems created or at least presented by education. The Joint Committee was created in 1911 as one phase of the awakening interest in public health which took place at that time and which gave birth to many if not most of the well known health movements of today. Before that time, interest of the public in health had been spasmodic and the principal attention given to public health questions had been by the medical profession.

Health has been placed first among the seven objectives of education. The Joint Committee in its earlier days met a great need for brief, inexpensive manuals for teachers on various phases of school health problems, such as sanitation, ventilation and lighting. The greatest contribution of the committee has been its manual *Health Education*,² which is now in its third revision and which has sold thousands of copies to teachers, who for many years relied on it as practically the sole textbook on health education. There are now numerous textbooks, but the Joint Committee's manual still maintains high rank as an authoritative document. The time is past when technical information needs to be given to the teacher by a joint committee. A crying need exists, however, for a declaration of policy with respect to the scope, extent and limitations of responsibility of the schools for the health of school children. In recognition of this need the Joint Committee has published a survey of opinions on school

2. *Health Education, A Program for Public Schools and Teacher Training Institutions*, 1930 edition, prepared by the Joint Committee on Health Problems in Education of the National Education Association and the American Medical Association (1937 revision in preparation).

health policies.³ At its last meeting, at New Orleans, a resolution was passed creating a special subcommittee to report not later than Nov. 1, 1937, with at least a tentative draft of a declaration, not of the views of others, but of opinions of the Joint Committee with respect to policies toward school health problems.

The symposium at Atlantic City, in which prominent physicians and health educators will participate, is planned as an opportunity to discuss matters of policy. Views expressed in this symposium may well have a considerable influence on the deliberations of the Subcommittee on Policy. All physicians interested in the health of school children and in the relation of school health policies to medical practice will be welcomed at the symposium. It will be held at 2 p. m. Tuesday, June 8, in the Music Room of the Hotel Chalfonte.

Current Comment

ROENTGEN IRRADIATION OF THE OVARIES IN MAMMARY CANCER

The existence of a relationship between the secretion of the ovaries and the growth and development of the mammary glands has been well established, both in man and in experimental animals. In man, this relationship is evident in the development of the breasts at puberty and subsequently in the rhythmic changes of the mammary gland during the menstrual cycle. That these changes are brought about chiefly by estrogen, secreted by the ovary, has been adequately demonstrated. Because of the growth promoting action of this factor on the mammary gland and because of the relatively high incidence of carcinoma of the breast during the period of greatest ovarian activity, many investigators have long suspected that there might exist a causal relationship between estrogen and mammary cancer. A considerable amount of recent experimental work appears to support such a view. For example, a number of compounds known to possess estrogenic properties are definitely carcinogenic under certain laboratory conditions.¹ Of particular interest in this connection is the recent observation² that the repeated injection of estrogenic substances into male mice frequently produces carcinoma of the mammary glands. Clinical reports that may be interpreted as suggestive of a relation between the ovaries and mammary cancer have appeared in the literature for many years. Indeed, as early as 1889, bilateral oophorectomy was declared³ to be beneficial in the treatment of the disease. Since that time numerous reports of an improvement in cancer of the breast following castra-

tion have appeared. With the discovery of the inhibitory effect of roentgen irradiation on the activity of the ovaries, this type of treatment has been substituted in some cases for the surgical removal of the glands. According to some investigators³ the results on the whole have been favorable. Consideration of the extensive and diverse evidence pointing to a relationship between the ovaries and the development of mammary cancer has recently led one investigator³ to suggest that roentgen irradiation of the ovaries, with the resulting elimination of estrogenic activity, may be beneficial as a supplement to radical mastectomy and radium therapy in the treatment of the disease. The value of this type of auxiliary therapy in the treatment of human mammary carcinoma, however, remains to be more adequately determined.

PROGRESS IN INTERNAL MEDICINE

So rapid is progress in medicine and so numerous are the publications recording that progress that few physicians can hope to keep constantly up to date even in special fields. For some time the *Archives of Internal Medicine* has been publishing monthly reviews of developments in many conditions. Already during 1937 Rackemann has reviewed the literature on allergy for 1936; Wilder and Wilbur have reviewed recent contributions to the subject of metabolism and nutrition, and in the April issue Greene and others have surveyed recent contributions to our knowledge of liver and biliary tract disease. Many physicians have found these collective reviews so useful that they have urged the publication of an annual volume containing this material. Physicians who are unacquainted with these succinct compilations and analyses of medical progress are neglecting a most useful addition to graduate education.

REGISTRATION UNDER HARRISON NARCOTIC ACT

On or before July 1, every physician registered under the Harrison Narcotic Act must reregister with the collector of internal revenue of each district in which he maintains an office or a place for the treatment of patients. Failure to reregister within the time allowed by law adds a penalty of 25 per cent to the annual narcotic tax payable at the time of registration and in addition makes the physician in default liable to a fine not exceeding \$2,000, or to imprisonment for not exceeding five years, or to both. While the Commissioner of Internal Revenue has been lenient in the past in enforcing the criminal penalties provided by the act for tardy registration, continued disregard on the part of some physicians of the requirement of the act with respect to reregistration will inevitably lead to criminal prosecutions. In recent years the commissioner has given some negligent or recalcitrant physicians the choice between paying substantial sums by way of compromise in lieu of the penalties for their offenses or, as an alternative, accepting criminal prosecution, with resultant publicity and liability to fines of indefinite amounts and possibly imprisonment. This was an act of grace on the part of the commissioner; under the

law he might have instituted criminal prosecutions without allowing the offending physicians any choice in the matter. Physicians must bear the requirements of the act in mind. If tardiness in registration results in criminal prosecutions, hereafter, they must recognize that ample notice has been given them.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ALABAMA

State Medical Election.—Dr. Edward S. Sledge, Mobile, was elected president of the Medical Association of the State of Alabama at its annual meeting in Birmingham, April 22. Dr. Alvin B. Coxwell, Monroeville, was reelected vice president of the southwestern division for four years, and Dr. Douglas L. Cannon, Montgomery, was reelected secretary. The next meeting of the association will be held in Mobile, April 19-21, 1938.

Personal.—Dr. William J. Craig, Shreveport, La., has been named health officer of Lawrence County.—Reuben T. Crawford, D.D.S., Montgomery, has been placed in charge of the reinstated division of oral hygiene of the bureau of hygiene and nursing of the state department of health. The bureau was abandoned during the depression on account of depleted funds.—Dr. Holland Thompson, formerly of the Maybury Sanatorium, Northville, Mich. (Detroit Municipal Tuberculosis Hospital), has been appointed tuberculosis clinician of the Alabama State Department of Health.—Dr. James O. Colley Jr., Troy, has been appointed physician to the Troy State Teachers College, succeeding Dr. William Shelby Sanders, resigned.—Dr. Albert C. Jackson, Jasper, was chosen president of the Alabama Hospital Association at its meeting in Birmingham, April 21.—Dr. Abraham I. Perley, Colemar, has been appointed health officer of Chambers County, effective May 1; he succeeds Dr. Chester E. Johnson Jr., who resigned to engage in private practice.

ARIZONA

Twenty Years as State Secretary.—The Arizona State Medical Association, at its annual meeting in Yuma, April 1-3, presented Dr. Delamere F. Harbridge, Phoenix, with a solid gold, diamond studded badge emblem, in appreciation of his having served twenty years as secretary of the organization.

Hospital News.—A new building will be erected for the county hospital in Phoenix, which will accommodate 200 patients.—A hospital is to be erected in Pima County, according to *Southwestern Medicine*. The WPA will furnish the labor, and \$10,000 will be made available from the relief fund for materials. Contracts were awarded April 17 for the hospital equipment, which will cost \$21,700.

CALIFORNIA

State Medical Election.—Dr. William W. Roblee, Riverside, was chosen president-elect of the California Medical Association at its annual meeting in Del Monte, May 5, and Dr. Howard Morrow, San Francisco, was inducted into the presidency. Dr. Frederick C. Warnshuis, San Francisco, was reelected secretary. The next annual session will be held at Pasadena, the date to be determined later.

Annual Tuberculosis Meeting.—The California Tuberculosis Association held its annual meeting at Riverside, April 2-3. One feature of the meeting was a symposium on silicosis, at which the speakers were Drs. Leroy U. Gardner, director, Saranac Laboratory for the Study of Tuberculosis, Saranac Lake, N. Y.; Royd R. Sayers, U. S. Public Health Service, Washington, D. C., and Anthony J. Lanza, assistant medical director, Metropolitan Life Insurance Company, New York.

Memorial Tablet to Dr. Mattison.—A bronze plaque was presented to the library of the Los Angeles County Medical Association, Los Angeles, May 13, in honor of the late Dr. Fitch C. E. Mattison, Pasadena. Mrs. Bess M. Behr, daughter of Dr. Mattison, unveiled the plaque. Speakers

included Paul Popenoe, D.Sc., and Drs. George H. Kress, Leroy B. Sherry and Harlan Shoemaker. Executed by Miss Maud Daggett, Pasadena, the plaque bears the portrait of Dr. Mattison, who at one time was president of the Los Angeles County Medical Association and, in 1913, of the California Medical Association. He died in 1932, aged 71.

COLORADO

Personal.—Dr. John A. Sevier, Colorado Springs, has been elected president of the Colorado Tuberculosis Association.

—Dr. Rudolph Albi, Denver, was recently appointed a member of the Colorado State Board of Medical Examiners succeeding Dr. Vardry A. Hutton, Florence, whose term expired April 3; Dr. Albi's term will end in 1943.—Dr. Morris Hinenburg, executive director of the Jewish Hospital, Brooklyn, N. Y., has been appointed superintendent and medical director of the Sanatorium of the Jewish Consumptives' Relief Society, Spivak, effective June 1.

Conference on Psychiatry.—At the request of several state hospital executives, a three day conference was held recently at the Colorado Psychopathic Hospital to discuss the recent advances in psychiatry, especially the insulin shock treatment of schizophrenia, fever therapy treatment and the possibilities of the additional use of state hospitals for teaching and research. Seventeen state hospital executives attended the conference, including the superintendents of each hospital in Nebraska, and representatives from Kansas, Wyoming, Utah, New Mexico, Washington and, in addition, staff members from the Colorado State Hospital at Pueblo.

CONNECTICUT

Personal.—Dr. Francis G. Blake, Sterling professor of medicine, Yale University School of Medicine, New Haven, was recently guest of honor at a birthday dinner. Dr. George Blumer, who preceded Dr. Blake as professor of medicine, was toastmaster.—Dr. Francis I. Nettleton has been appointed health officer of Shelton.

Study of Infant and Maternal Mortality Rates.—The Hartford Board of Health has authorized its president, Dr. George E. Cogan, to appoint a committee to study a plan whereby all infant and maternal deaths in the city would be reviewed at regular meetings of the obstetric and pediatric services of the city's four hospitals. According to the *New England Journal of Medicine* the plan was proposed by Dr. James R. Miller before the Hartford Medical Society, February 15. Its objective is to establish quarterly meetings to review these deaths as reported by the board of health. Similar plans in New Jersey and Ohio have been effective in reducing the mortality rates, it was stated.

DISTRICT OF COLUMBIA

In Memory of Dr. Wilmer.—A bronze plaque was unveiled in the Chapel of St. Joseph of Arimathea, Washington, D. C., recently, in tribute to Dr. William Holland Wilmer, professor of ophthalmology, Georgetown University School of Medicine, 1906-1925. In 1925 Dr. Wilmer became professor of ophthalmology at Johns Hopkins University School of Medicine, Baltimore; ophthalmologist in chief at Johns Hopkins Hospital, and director of the Wilmer Institute, which was created as a tribute to him by patients and friends. He retired from these positions in 1934 and died March 12, 1936, aged 72.

FLORIDA

Dade County Society and Dr. Mark White.—The legislative committee of the Dade County Medical Society, Miami, voted, April 14, "to keep Dr. Mark White out of Florida," unless he returns to serve a sentence received on his conviction of practicing medicine without a license in the state, a charge to which he is said to have pleaded guilty in June 1936. In February 1937 when it was ascertained that his bulletins "The Thyroid and Other Ductless Glands" were being sent through the mail to physicians, a complaint was filed, but White left that night by plane for Oklahoma and Chicago. According to the records of the Association, White is reported to have graduated from the St. Louis College of Physicians and Surgeons in 1910 and licensed to practice in Iowa in 1918 and in Oklahoma in 1919 by reciprocity with Iowa. In 1919 the Illinois State Department of Registration refused him a license. In 1926 it was reported that he had been convicted in the court of the mayor of Ashland, Ohio, for the illegal practice of medicine and surgery and fined \$100 and costs. In April 1936 an information card returned to the Association headquarters indicated that he was practicing in Florida.

ILLINOIS

Lectures on Obstetrics and Pediatrics.—Two talks by Drs. Charles E. Galloway, Evanston, and John A. Bigler, Highland Park, May 26, will conclude the series of lectures on obstetrics and pediatrics which have been given throughout the state recently. Their subjects are, respectively, "Treatment of Abortions" and "Tuberculosis." When the present series ends, thirty lectures will have been given in groups of six each in Dewitt, Logan, Sangamon, McLean, Menard, Mason, Fulton and McDonough counties. It is hoped to resume the series in the fall. Dr. Harold H. Hill, formerly associate in the department of obstetrics and gynecology, University of Illinois College of Medicine, as field consultant, is in charge of arrangements for these lectures, which are a part of a national program to improve conditions of mothers and children in rural areas.

Chicago

Personal.—Dr. Disraeli W. Kobak has received from Belgium the diploma and insignia of a commander of the Royal Order of St. George in recognition of his work in physical medicine.—Dr. Max Thorek has been made a corresponding member of the National Academy of Medicine of Colombia, South America.

Survey of Air Pollution.—A survey of air pollution in Chicago is under way, with I. A. Deutch, combustion engineer for the city's smoke abatement department, and Alamjit D. Singh, M.S., of the University of Illinois, Urbana, in charge. The tests will show the amount of sulfur dioxide and carbon and other dust particles in the air, it was reported.

Second Annual Hobby Show.—The Chicago Medical Society held its second annual hobby show in the lounge of the Medical and Dental Arts Building, April 7-8. About fifty physicians had entries in the exhibit, which, during the two days, had an attendance of about 1,500 persons. Wednesday evening, Dr. Louis J. Tint gave an illustrated lecture on "Tropical and American Gardens" and "Some Views of the Cascade Range," all photographed in natural colors, and Dr. Frank P. Thompson displayed motion pictures of his recent hunting trip to Africa. Dr. Carl O. Schneider lectured Thursday evening on Bryce Canyon National Park and garden and flower scenes, which were illustrated by direct color photography, and Dr. Julius H. Hess presented a natural color motion picture of Chicago. Among the exhibits were stamp collections, paintings, camera studies and wood work, a collection of mounted specimens of leaves of common weeds that transmit hay fever, and plaster studies in obstetric anatomy.

INDIANA

Officers of State Tuberculosis Association.—Dr. Charles J. McIntyre, Indianapolis, was elected president of the Indiana Tuberculosis Association at its annual meeting in Indianapolis, April 15. Other new officers are Dr. Maurice R. Lohman, Fort Wayne, and Woodson S. Carlisle, South Bend, vice presidents; Dr. Edward M. Amos, Indianapolis, treasurer, and Mrs. William Greemelstacher, Logansport, secretary.

Immunization Campaign in Schools.—A three weeks campaign against diphtheria and smallpox was launched in the thirty-three public and parochial schools of South Bend the first week of May. Records of various classrooms will be kept and awards made to those showing the greatest improvement in percentages of children immunized and vaccinated. The drive is sponsored by the city health department.

Society News.—Dr. Ross C. Ottinger, Indianapolis, discussed the "Importance of Pelvic Examinations" before the Knox County Medical Society in Vincennes, April 13.—The Fort Wayne Medical Society was addressed in Fort Wayne, April 6, by Dr. Ward F. Seeley, Detroit, on "Heart Disease and Pregnancy from the Viewpoint of the Obstetrician."—At a meeting of the Floyd County Medical Society in New Albany, April 9, Dr. Gretchen Irene Polhemus, New Albany, spoke on allergy.

KANSAS

Dr. Earle Brown Goes to Virginia.—Dr. Earle G. Brown, for twelve years secretary and executive officer of the Kansas State Board of Health, Topeka, has resigned to become health officer of Arlington, Va., it is reported. The change was effective May 1. Dr. Brown graduated from Northwestern University Medical School, Chicago, in 1913. He engaged in private practice from 1914 to 1917 and served as health officer of Topeka from 1919 to 1925. He was president of the Conference of State and Provincial Health Authorities of North

America in 1936 and of the Kansas Medical Society in 1927. Dr. Harry R. Ross, head of the division of child hygiene, will serve temporarily as secretary of the board, pending the election of a successor to Dr. Brown.

KENTUCKY

Portrait of Daniel Drake.—The Fayette County Medical Society, Lexington, has acquired a portrait of Dr. Daniel Drake, dean of Transylvania Medical College, Lexington, from 1819 to 1829 and author of a famous treatise on "Principal Diseases of the Interior Valley of North America." The portrait has been for 100 years in the possession of a Carter family in Versailles, descendants of Dr. Joseph C. Carter, for many years an intimate friend of Dr. Drake.

Society News.—Drs. William D. Haggard and William R. Cate, Nashville, addressed the Christian County Medical Society, Hopkinsville, April 20, on "Consideration of Fibroid Tumors of the Uterus" and "The Elderly Thyrocardiac" respectively.—Drs. Joseph A. Bowen, Louisville, and Carl C. Howard, Glasgow, addressed the Muldraugh Hill Medical Society, April 8, in Elizabethtown on "Cause and Effect of Kidney Infection" and "Blood Infections."—Drs. Robert Lyle Motley and Thomas D. Moore, Memphis, Tenn., addressed the Fulton County Medical Society, Hickman, on cardiac edema and lesions of the kidney, respectively.—A symposium on arthritis was presented before the Jefferson County Medical Society, Louisville, April 19, by Drs. Arthur C. McCarty, David E. Jones and Richard T. Hudson.—Dr. Randall Dow Collins, Whitesburg, addressed the Letcher County Medical Society, Whitesburg, March 30, on "Syphilis—A Community Health Problem."

LOUISIANA

Longer Life Week.—The Orleans Parish Medical Society conducted its annual "Longer Life Week" May 17-22, placing special emphasis on cancer. A special meeting of the society the first day of the campaign was devoted to a symposium on malignancy. This year the local dental society cooperated in the campaign and presented a symposium on cancer about the month May 19. At both meetings the March of Time film on cancer was shown. Dr. Edward William Alton Ochsner, New Orleans, was chairman of the Longer Life Week Committee this year. Appendicitis was the theme of the society's program in 1936.

MARYLAND

Conference of Health Boards.—The seventeenth annual conference of health officers and boards of health of Maryland was held at Johns Hopkins School of Hygiene and Public Health, Baltimore, May 14. The speakers included:

Dr. Allen W. Freeman, A Review of Tuberculosis in Maryland.
Dr. Roderick Heffron, Boston, The Massachusetts Pneumonia Program.
Mark Welsh, D.V.M., Maryland Program for Control of Bang's Disease.
Miss Katherine F. Lenroot, chief, U. S. Children's Bureau, Washington, D. C., Federal and State Cooperation in Promoting Maternal and Child Health.
Dr. Leroy E. Burney, U. S. Public Health Service, Washington, D. C., Some Problems in the Control of Syphilis.

Dr. Tillett Goes to New York University.—Dr. William Smith Tillett, since 1930 associate professor of medicine at Johns Hopkins University School of Medicine, Baltimore, has been appointed professor of bacteriology and director of the bacteriologic laboratories at New York University College of Medicine, New York. A native of Charlotte, N. C., and 44 years of age, Dr. Tillett graduated from Johns Hopkins in 1917. From 1922 to 1930, when he joined the staff of his alma mater, Dr. Tillett served as assistant and associate at the Rockefeller Institute Hospital, New York, and during the past year president of the American Society of Clinical Investigation.

MASSACHUSETTS

Sedgwick Lecture.—Selskar Michael Gunn, C.P.H., vice president of the Rockefeller Foundation and director of public health of the foundation in the Far East, delivered the thirteenth William Thompson Sedgwick Memorial Lecture of the Massachusetts Institute of Technology, April 23, on "Public Health Work in China."

Physician on Arctic Expedition.—Dr. Kenneth W. Sewall, resident physician at Massachusetts Memorial Hospitals, has been appointed physician and surgeon to the expedition that Lieut.-Comdr. Donald B. MacMillan will lead to the arctic this summer, according to *New England Journal of Medicine*. The expedition, consisting of thirty-five scientists and students, will sail from Boston on the *Gertrude L. Thayer*, June 19, it is reported. Dr. Sewall graduated from Harvard University Medical School in 1934.

Society News.—The Boston Society for the Advancement of Gastroenterology was addressed, May 7, among others, by Drs. Harry Parks on "Treatment of Patients with Gastro-Intestinal Hemorrhage" and George Levene, "Experience with the Double Oral Method of Cholecystography."—The Harvard Medical Society was addressed in Boston, April 27, by Milan A. Logan, Ph.D., on "The Calcium Salts of Bone" and A. Baird Hastings, Ph.D., "Salt and Water Exchange Between Tissues and Body Fluids."—Dr. Emery A. Rovenstine, New York, discussed "Abdominal Reflex Complicating Anesthesia: Laboratory and Clinical Investigations" before the Boston Society of Anesthetists, April 6.—Dr. Thomas Archibald Malloch, New York, discussed "A Vesalian Miscellany" before a joint meeting of the Boston Medical History Club and the Boston Medical Library, April 26.

Industrial Health Problems.—Sections on industrial health problems and medical service in industry were included in the program of the sixteenth annual Massachusetts Safety Conference at the Hotel Statler, Boston, April 5-6. The following participated in the section on industrial health problems:

Manfred Bowditch, director, Massachusetts Division of Occupational Hygiene, The National Silicosis Conference of 1936-1937.
Herbert I. Miller of the Missouri State Board of Health, Ventilation Requirements in Metal Spraying.
William P. Yant, B.S., director of research, Mine Safety Appliances Company, Pittsburgh, The Occurrence and Effects of Industrial Gases.

Philip Drinker, Ch.E., professor of industrial hygiene, Harvard University School of Public Health, led the discussion. Speakers on medical aid in industry were:

Dr. William E. Browne, Boston, The Neglected Scratch.
Dr. John D. Adams, Boston, The Strained Back.
Dr. Nels A. Nelson, division of communicable diseases, state department of public health, The Relation of Gonorrhea and Syphilis to the Industrial Accident.

MICHIGAN

Max Ballin Memorial Lectures.—Dr. Russell L. Haden, Cleveland, opened the fourth annual series of the Dr. Max Ballin Memorial Lectures, April 28, with a talk on "The Clinical Approach to Hematology." Drs. Elwood A. Sharp and William H. Gordon, both of Detroit, spoke May 5 on "Evaluation of Hematopoietic Drugs" and "Blood Dyscrasias Associated with Specific Lesions in the Throat" respectively. Other speakers in the series, which is sponsored by the North End Clinic, Detroit, include:

Dr. Nathan Rosenthal, New York, May 12, The Purpuras, Hemophilia and Other Hemorrhagic States.
Dr. Raphael Isaacs, Ann Arbor, May 19, Clinical Hematologic Aspects of Disease of the Lymph Glands and Spleen.
Drs. Thomas B. Cooley and Louis D. Stern, both of Detroit, May 26, Anemias of Childhood and Pregnancy, respectively.
Dr. Richard H. Jaffe, Chicago, June 2, Clinical Interpretation of Bone Marrow Studies in Diseases of the Blood.

Society News.—Dr. Reed M. Nesbit, Ann Arbor, discussed "Urinary Tract Infections" before the Genesee County Medical Society in Flint, May 5.—Dr. Bruce H. Douglas, Detroit, discussed "Tuberculosis Case Finding and the Private Physician" before the Washtenaw County Medical Society in Ann Arbor, April 13.—At a meeting of the Oakland County Medical Society, April 7, Dr. Lawrence Reynolds, Detroit, spoke on "Roentgenological Studies of Gastro-Intestinal Diseases."—Dr. Udo J. Wile, Ann Arbor, addressed a joint meeting of the Detroit Pediatric and Dermatology societies, April 6, on "Congenital Syphilis." Dr. Perrin H. Long, Baltimore, addressed the pediatric society, May 5, on "The Treatment of Beta Hemolytic Streptococcal and Other Infections with Sulfanilamide (Prontosil and Prontylin) or Their Derivatives."—Dr. Austin A. Hayden, Chicago, addressed the Berrien-Cass County Medical Society in Benton Harbor, April 21.—At a meeting of the Muskegon County Medical Society, Muskegon, April 16, Dr. Norman R. Kretschmer, Ann Arbor, discussed "Clinical Aspects of Endocrinology."—Dr. William S. Sadler, Chicago, addressed the Calhoun County Medical Society in Battle Creek, April 6, on "Psychiatric Aspects of Medical Practice."

MINNESOTA

Personal.—Dr. Elmer J. Lillehei, Robbinsdale, has been made director of the Hennepin County Tuberculosis Association.—Plans are under way to form a voluntary subscription fund to establish a memorial to the late Dr. Oscar E. Locken, mayor of Crookston.—Dr. David M. Parker, formerly a physician in the CCC, has been appointed health officer of Virginia to succeed Dr. John A. Malmstrom, resigned, according to the *Journal-Lancet*.

Illegal Practitioner Sentenced.—R. A. McHale, Long Prairie, was recently sentenced to four months at hard labor in the Todd County jail, following his conviction on the charge

of practicing healing without a basic science certificate. According to the Minnesota State Board of Medical Examiners, evidence in the trial showed that McHale represented himself as "Dr." McHale and that he told numerous persons he was a chiropractor. The evidence showed that McHale examined patients, prescribed diets, administered manipulation and light treatments and furnished salve and pills for the treatment of diseases, charging some patients \$2 per treatment and others a flat price of \$10.

MISSISSIPPI

Meeting of the Thirteen County Society.—The North-east Mississippi Thirteen-County Medical Society held its first quarterly meeting in Booneville, March 16, with Dr. Luther L. McDougal Sr., Booneville, presiding. The program included:

Dr. Emile Q. Withers, Columbus, Diseases of the Nose and Throat.
Dr. LeRoy B. Brackstone, Iuka, Acute Hemorrhagic Nephritis in Children.
Dr. Isidore Cohn, New Orleans, Differential Diagnosis and Surgical Indications in Splenomegaly.
Dr. John Gould Gardner, Columbia, Infection of the Hand.

Following a banquet, Dr. George A. Hendon, Louisville, discussed "The Public's Relationship with the Medical Profession."

NEW JERSEY

State Medical Election—Dr. Morrison Resigns as Secretary.—Dr. William J. Carrington, Atlantic City, was chosen president-elect of the Medical Society of New Jersey at its annual meeting in Atlantic City, April 28, and Dr. William G. Herrman, Asbury Park, was installed as president. Dr. Alfred Stahl, Newark, was elected secretary to succeed Dr. John B. Morrison, Newark, who resigned after fifteen years' service in the position. Atlantic City was designated as the place for the next annual meeting. Dr. Morrison, who is 71 years of age, graduated from Columbia University College of Physicians and Surgeons in 1895. Dr. Stahl graduated from Baltimore Medical College in 1906; he is 57 years of age. All communications pertinent to the society should be addressed to him at the executive offices, 143 East State Street, Trenton.

NEW MEXICO

Hospital for Crippled Children to Be Dedicated.—The Carrie Tingley Hospital for Crippled Children will be dedicated at Hot Springs, May 29, and is expected to be ready for occupancy about the middle of June. When completed the hospital will have cost about \$800,000, furnished by WPA funds, state aid and the town of Hot Springs. The building is Spanish colonial in style, covering 1.8 acres floor space and so designed that another story may be added. The main section is two stories with the second floor prepared for the use of the staff only. Three wings extend from the main section of combined dining and recreation room, offices and directors' room, and an operating wing has facilities to retain the patient until he has recuperated. Speakers in the dedicatory ceremonies include Governor Clyde Tingley, Postmaster General James A. Farley and Elliott Roosevelt.

NEW YORK

Medical Women's Meeting.—The thirty-first annual meeting of the Women's Medical Society of New York will be held at the Century Club, Rochester, May 24, under the presidency of Dr. Elise S. L'Esperance. Speakers will include:

Drs. Martha E. Howe and Hayes E. Martin, New York, Glossitis Rhombica Mediana.
Dr. Margaret Warwick, Buffalo, Causes of Death in New-Born Infants.
Dr. Marguerite P. McCarthy, Solvay, Pylorus Spasm, an Infantile Allergic Manifestation.
Dr. Martha Brunner-Ornstein, Vienna, Newer Researches in Physical Medicine.

New York City

Appointments at Columbia.—The following appointments to the staff of Columbia University College of Physicians and Surgeons have recently been announced:

Dr. William H. Stewart, to be clinical professor of radiology.
Dr. George Gray Ward, clinical professor of obstetrics and gynecology.
Drs. Albert H. Aldridge and Ralph A. Hurd, assistant clinical professors of obstetrics and gynecology.
Dr. Earl E. Van Derwerker, assistant professor of clinical orthopedic surgery.
Dr. John E. Scarff, assistant professor of neurologic surgery.

Kober Medal Awarded to Dr. Park.—Dr. William H. Park, director emeritus of laboratories of the New York City Department of Health, was awarded the annual George M.

Kober medal by the Association of American Physicians at its annual meeting in Atlantic City, May 5. Dr. Park was cited for his research work in infectious diseases and immunity to them. It was announced that Dr. Rufus Cole, director of hospitals of the Rockefeller Institute, would be the recipient of the medal next year. Dr. Park, who is 74 years of age, officially retired from the department of health laboratories last year. He had been director since 1894. He also retired last year as Herman M. Biggs professor of preventive medicine with the title of emeritus at the New York University College of Medicine.

Society News.—Drs. Walter G. Lough, Herman O. Mosenthal and George J. Heuer presented papers on hypertension at a meeting of the New York Physicians-Yorkville Medical Society, March 24.—The program of the Medical Society of the County of New York, March 22, was devoted to discussion of venereal disease, with the following speakers: Drs. Howard S. Jeck, Abraham L. Wolbarst, Terry M. Townsend, Frederic Bierhoff and Charles Walter Clarke.—Drs. Leo Spiegel and Theodore Rosenthal addressed the Bronx County Medical Society, March 18, on "Modern Treatment of Syphilis" and "Modern Public Health Control of Syphilis" respectively.—Dr. Otho C. Hudson, Hempstead, was chosen president elect of the Associated Physicians of Long Island at its annual meeting recently and Dr. Charles A. Anderson, Brooklyn, became president.

OHIO

University of Cincinnati News.—Dr. Erl A. Baber has been advanced to assistant professor of psychiatry at the University of Cincinnati College of Medicine.—An anonymous gift of \$20,000 has been given to the University of Cincinnati College of Medicine, to be used for equipping an "added isolation unit at the general hospital for a particular purpose."—Dr. Martin H. Fischer gave an "appreciation lecture" in the students series, May 7; his subject was "Form."

Personal.—Dr. Roy C. Rehder, assistant health commissioner of Mansfield, has been made commissioner to succeed Dr. Milard C. Hanson, who has been appointed health officer of Toledo.—Dr. Murray N. Fowler of the staff of the Athens State Hospital has been appointed medical superintendent at the Applecreek Institution for Feeble-minded, succeeding Dr. Lorne W. Yule, who resigned in October 1936.—Dr. Walter M. Simpson, Dayton, was made a member of the Legion of Honor of France during the recent International Congress on Fever Therapy in New York, in recognition of his research on artificial fever.

OKLAHOMA

Society News.—Dr. Erma O. Johnson, Tulsa, addressed the Tulsa County Medical Society, Tulsa, April 12, on "Practical Endocrine Therapy in Gynecology."—The Kingfisher County Medical Society was recently organized with Drs. John T. Anglin, Dover, as president and Frank C. Lattimore, Kingfisher, as secretary.—At a meeting of the Carter County Medical Society in Ardmore, April 5, the speakers were Drs. Robert C. Sullivan, Ardmore, on "Buerger's Disease"; Charles A. Brake, Norman, "Chronic Alcoholism in the Hebeephrenic Stage," and Ben H. Cooley, Norman, "Coronary Thrombosis."—At a recent meeting of the Oklahoma County Medical Society, Oklahoma City, the speakers were Drs. Carroll M. Pounders, on the panel system of medicine in England; Edward C. Mason, physiology of kidney function; Hugh G. Jeter, pathology of nephritis, and Basil A. Hayes, urology as an aid in treatment of nephritic symptoms.

OREGON

New President of State Society.—Dr. Charles E. Sears, Portland, first vice president of the Oregon State Medical Society, was elected president of the society at a meeting of the council, March 24, to succeed Dr. Thomas W. Watts, Portland, who resigned because of ill health. Dr. Watts died March 26.

PENNSYLVANIA

Campaigns Against Diphtheria.—An immunization campaign against diphtheria among children of preschool age was carried on by the Lycoming County Medical Society, May 17-22. Children of parents unable to pay will be immunized the following week, which has been designated "clinic week." It is planned to set up clinics in various centers where members of the society may perform the work. Immunization of school children was begun in Erie County, May 1, as a part of the spring and summer health round up.

Philadelphia

Personal.—Dr. Alfred N. Richards, professor of pharmacology, University of Pennsylvania School of Medicine, has been elected a trustee of the Rockefeller Foundation.

Society News.—Dr. Alphonse R. Dochez, New York, delivered a Mary Scott Newbold lecture at a meeting of the College of Physicians of Philadelphia, May 5, on "Agents of Upper Respiratory Infections."—Dr. Samuel A. Levine, Boston, was the guest speaker at the annual meeting of the Philadelphia Heart Association, April 28, on "Auscultation of the Heart." Dr. David Riesman, chairman of the executive committee, reviewed the year's work. Dr. William D. Stroud was reelected president.

TEXAS

State Medical Election.—Dr. Ernst W. Bertner, Houston, was elected president of the Texas State Medical Association at its annual meeting in Fort Worth recently. Vice presidents are Drs. Craig W. Munter, Fort Worth, Robert B. Touchstone, Lytle, and Harry L. Locker, Brownwood, and Dr. Holman Taylor, Fort Worth, was reelected secretary. The next annual meeting will be held in Galveston.

Personal.—Dr. John W. Tappan, El Paso, has been appointed health officer of the El Paso city and county health unit, succeeding Dr. Thomas J. McCamant. Dr. John W. Brown, Austin, state health officer for the past four years, has been appointed health officer of Houston. Dr. Milton C. Williams, San Marcos, has been appointed health officer of Hays County and Dr. Philip S. Joseph, Alice, reelected health officer of Jim Wells County. Dr. Jesse E. Ross Jr., Henderson, has been named health officer of Rusk County and Dr. Jack E. Frost, DeKalb, of Bowie County.

VIRGINIA

Personal.—Dr. Williamson C. Welburn, Arlington, has been appointed health officer of Arlington County to succeed Dr. Peyton M. Chichester, Clarendon, who has been appointed to the staff of the state health department.—Dr. Irl T. Riggan, Richmond, state commissioner of health, will receive the honorary degree of doctor of science at the coming commencement of the Medical College of Virginia.

Promotions at the Medical College.—The following promotions in the faculty of the Medical College of Virginia, Richmond, were recently announced:

Dr. Emmett H. Terrell to professor of clinical proctology.
Everett H. Ingersoll, Ph.D., to associate professor of anatomy.
Dr. Paul Kimmeltiel to associate professor of pathology.
Dr. Emanuel U. Wallerstein to associate professor of otolaryngology.
Dr. James P. Baker Jr. to assistant professor of medicine.
Dr. Ernst Fischer to associate professor of physiology and pharmacology.
Dr. Andrew Stephens Graham to assistant professor of surgery.
Dr. Randolph H. Hoge to assistant professor of surgery and gynecology.
Dr. Thomas D. Jones to assistant professor of pediatrics.
Dr. Kinloch Nelson to assistant professor of medicine.
Dr. James B. Stone to assistant professor of pediatrics.
Dr. George Z. Williams to assistant professor of pathology.
Dr. John H. Scherer to assistant professor of medicine.
Dr. John Blair Pitts to assistant professor of orthopedic surgery.
Dr. Donald M. Faulkner to associate professor of orthopedic surgery and chief of clinic.
Dr. Henry Page Mauck to professor of clinical orthopedic surgery.

WISCONSIN

Council on Scientific Work.—A council on scientific work has been organized to supersede the program committee of the State Medical Society of Wisconsin. Members of the new council are Drs. William S. Middleton, Madison, chairman; George W. Krahn, Oconto Falls; Henry A. Sincok, Superior; James A. Evans, La Crosse, and Eben J. Carey, Milwaukee.

New Graduate Course.—A series of graduate lectures in obstetrics and pediatrics was begun April 12. A session will be held one afternoon each week for six weeks in Janesville, Racine, Waukesha, Sheboygan and Beaver Dam. Drs. John W. Harris, professor of obstetrics and gynecology, and John E. Goncz Jr., professor of pediatrics, University of Wisconsin Medical School, Madison, are the instructors of the course which is sponsored by the state health department.

Council to Plan Venereal Disease Control.—Governor La Follette has appointed a "planning council" to further a program for the control of venereal disease in Wisconsin. Dr. William F. Lorenz, Madison, is chairman and Mr. J. George Crownhart, executive secretary of the State Medical Society of Wisconsin, is secretary of the council. The members are Drs. Cornelius A. Harper, Madison, state health officer, and Harry M. Guilford, bureau of communicable diseases, state board of health; and all members of the state medical society's committee on venereal diseases, Drs. James C. Sargent, Edward L. Tharinger and William J. McKillip.

all of Milwaukee, Gunnar Gundersen, La Crosse, and Charles W. Giesen, Superior. The work of the council will be to coordinate the forces and advise the governor with respect to developments, participation by state forces and legislation.

GENERAL

Neisserian Society Meeting.—The third annual meeting of the American Neisserian Medical Society will be held in Atlantic City, June 8, at the Hotel Senator. Dr. Thomas Parran, surgeon general, U. S. Public Health Service, Washington, D. C., will give his presidential address on "Present Needs in the Public Health Control of Gonorrhea," and the guest speaker will be Dr. John L. Rice, health commissioner of New York City, on "The Essential Elements in a Program for Control of Gonorrhea."

American Dermatological Association.—The sixtieth annual meeting of the American Dermatological Association will be held at the Skytop Lodge, Cresco, Pa., under the presidency of Dr. John H. Stokes, Philadelphia. The speakers will include:

- Dr. Andrew M. Davidson, Winnipeg, Man., Use of Quinine Bisulfate in the Treatment of Lupus Erythematosus.
- Dr. George W. McCoy, Washington, D. C., The Communicability of Leprosy.
- Dr. Udo J. Wile, Ann Arbor, Mich., Sex Hormone Studies in Acne.
- Dr. Paul E. Bechet, New York, Deciduous Skin.
- Dr. Robert E. Barney, Cleveland, Zosteriform Leukemia Cutis.

Meetings in Atlantic City.—The medical alumni of the University of Pennsylvania will hold a smoker and vaudeville at 9 p. m. at the Hotel Jefferson, Atlantic City, June 9, and not the Hotel Madison as previously announced. The joint luncheon of the Medical Veterans of the World War and the New Jersey chapter of the Association of Military Surgeons of the United States will be held at the Hotel Ambassador, June 8. The annual dinner of the medical alumni of Northwestern University Medical School, Chicago, will be held Wednesday evening, June 9, at 6:30 at the Traymore Hotel. The annual luncheon of Phi Lambda Kappa Fraternity will be held Wednesday noon, June 9, at the Ritz-Carlton Hotel.

Delay in Publication of Pharmacopeia Supplement.—Changes in plans for the binding of the First Supplement to the Pharmacopeia of the United States, Eleventh Decennial Revision, have caused a slight delay in its appearance, the committee announces. It was planned to issue the supplement in a paper cover enclosed in a spring back binder capable of holding similar supplements in the future. However, it has been decided to bind it in a more substantial but flexible cover. The delay in the release of the first supplement will no doubt necessitate an advance in the date when the new standards are to become official. Orders should be sent to the Mack Printing Company, Easton, Pa., or to any of the regular distributing agencies for the Pharmacopeia. The price will be \$1.

Medical Library Association in Richmond.—The thirtieth annual meeting of the Medical Library Association will be held in Richmond, May 23-26, in the auditorium of the Richmond Academy of Medicine. Among papers to be presented will be "The Value of Old Books in a Medical Library," by Dr. Marvin Pierce Rucker, Richmond; "Plantation Medicine," Miss Mary Louise Marshall, librarian of Tulane University of Louisiana School of Medicine, New Orleans, and "Medicine and Shockoe Hill," Dr. Harry J. Warthen Jr., Richmond. William T. Sanger, LL.D., president of the Medical College of Virginia, will preside at the annual dinner, at which Dr. William W. Francis, Montreal, Que., president of the association, will deliver his official address.

American Gynecological Society.—The sixty-second annual meeting of the American Gynecological Society will convene at the New Ocean House, Swampscott, May 31-June 2, under the presidency of Dr. Frederick J. Taussig, St. Louis. Speakers will include:

- Dr. Lillian K. P. Farrar, New York, Upper Pelvic Floor, and Its Importance in Total Abdominal Hysterectomy.
- Dr. Harvey B. Matthews, Brooklyn, The Continuous Auscultation of the Fetal Heart by Means of An Amplifying Stethoscope (preliminary report).
- Dr. Robert A. Ross, Durham, N. C., Observations Pertinent to Gonadotropic Therapy in Gynecology.
- Dr. Franklin L. Payne, Philadelphia, The Clinical Significance of Endometrial Hyperplasia.
- Dr. Guy L. Hunner, Baltimore, An Unusual Obstetrical Injury, Detaching Bladder and Urethra from the Symphysis Pubis and Causing Complete Epispadias.
- Dr. Henry Close Hesselbine, Chicago, Biologic and Clinical Import of Vulvovaginal Mycosis.

Academy of Pediatrics.—The seventh annual meeting of the American Academy of Pediatrics will be held at the Waldorf-Astoria Hotel, New York, June 3-5. Thursday will be given over to a series of round table discussions on anemia,

asthma, childhood psychiatry, common skin diseases, diabetes, eczema, gonococcal infection, meningococcal meningitis, nephritis, poliomyelitis, sedimentation rate, speech defects, treatment of empyema and vitamins. Dr. Alexis F. Hartmann, St. Louis, will speak Friday morning on "Hypoglycemia in Infancy and Childhood" and Dr. Alfred H. Washburn, Denver, "Diverse Attributes of Healthy Children." Panel discussions will be held Friday afternoon on "Present Status of Active Immunization Against Scarlet Fever" and "Present Status of Active Immunization Against Whooping Cough."

Bronchoscopic Society Meeting.—The American Bronchoscopic Society will hold its twentieth annual meeting at the Marlborough-Blenheim Hotel, Atlantic City, June 2, under the presidency of Dr. Joseph C. Beck, Chicago, who will deliver his address in the afternoon on "Standards in the Practice of Bronchoscopy." In addition to case reports, papers will be read by:

- Dr. Thomas E. Carmody, Denver, Interesting Endoscopic Cases.
- Dr. John D. Kernan, New York, Tuberculous Lesions of the Trachea and Bronchi.
- Dr. John H. Foster, Houston, Texas, Treatment of Laryngeal Papillomatosis.
- Dr. Sobieska S. Hall, Clarksburg, W. Va., Bronchoscopic Aspects of Lung Abscess.
- Dr. Evan G. Galbraith, Toledo, Experimental Bronchial Obstruction.
- Dr. Waitman F. Zinn and William F. Rienhoff Jr., Baltimore, Diagnosis and Treatment of Primary Bronchial Carcinoma.
- Dr. Chevalier Jackson, Philadelphia, The Bronchoscope and the American Bronchoscopic Society and the Technic of Bronchography.

Meeting of Ophthalmologists.—The American Ophthalmological Society will hold its seventy-third annual convention at The Homestead, Hot Springs, Va., June 3-5. Speakers will include:

- Dr. Martin Cohen, New York, Bilateral Metastatic Carcinoma of the Choroid.
- Dr. Frederick T. Tooke, Montreal, Canada, Case of a Melanoma of the Iris with Microscopic Findings.
- Drs. Hans Barkan and Horace Gray, both of San Francisco, The Eye and Diabetes.
- Drs. Samuel Hanford McKee and Francis L. McNaughton, Montreal, Neuromyelitis.
- Dr. Jonas S. Friedenwald and Robert D. Stiehler, Ph.D., Baltimore, The Mechanism of Formation of the Aqueous.
- Drs. Sylvester Judd Beach and William R. McAdams, both of Portland, Maine, Benzedrine-Homatropine Cycloplegia.

At the executive session, Thursday evening, Dr. David Harrower, Worcester, Mass., will read a paper on "The Early Formation of the American Ophthalmological Society."

Mosquitoes Imported on Airplanes.—*Public Health Reports* announces the results of sixty-nine inspections made by officers of the U. S. Public Health Service at Miami during one month. The inspections were made to determine the presence of mosquitoes transported from South America and no insects were found in forty-five instances. In the other twenty-four inspections, fifty-three insects were captured and one escaped. In seven of the twenty-four inspections thirteen mosquitoes were found, ten of which were dead. The maximum number of mosquitoes found during a single inspection was three, of which two were dead. Of the thirteen mosquitoes ten were identified as follows: *Aedes sollicitans*, 1; *Culex*, species unidentified, 1; *Culex quinquefasciatus*, 3; *Culex* inhibitor, 1; *Mansonia indubitans*, 1; *Mansonia titillans*, 3. Three mosquitoes were unidentified. The report points out that, while no yellow fever mosquitoes were discovered on the inspections, the list shows that such mosquitoes might easily be brought into this country by airplanes unless adequate measures are observed to prevent their importation.

Meeting of Ear, Nose and Throat Society.—The forty-third annual session of the American Laryngological, Rhinological and Otolological Society will be held at the Hotel Traymore, Atlantic City, June 3-5. Among others, the following will present papers:

- Dr. C. Coulter Charlton, Atlantic City, Climate and the Upper Respiratory System.
- Dr. Ralph A. Fenton, Portland, Ore., Management of Blood Stream Infections from Mastoiditis.
- Drs. James A. Babbitt and Damon B. Pfeiffer, both of Philadelphia, Myxoma of the Palate and Pharynx, with Report of a Special Case.
- Dr. Edmund Prince Fowler, New York, The Hearing Before and After Radical Mastoidectomy; A Plea for Less Radical Middle Ear Surgery; Fifty Cases, with Audiograms, Clinical and X-Ray Findings.

Dr. Henry Lane Williams Jr., Rochester, Minn., will present the candidate's thesis by title Saturday morning on "Otitic Hydrocephalus." The annual dinner will be held Friday evening.

Society of Clinical Pathologists.—The sixteenth annual meeting and fourth seminar of the American Society of Clinical Pathologists will be held at the Hotel Bellevue-Stratford, Philadelphia, June 2-5. Dr. Roy R. Kracke, Emory University, Ga., will deliver his presidential address Saturday morning on "The Future of Pathology." The principal speaker

at the banquet Saturday evening will be Dr. George P. Müller, Philadelphia, whose subject will be "Surgical Pathology." Speakers will include:

- Dr. Richard P. Custer, Philadelphia, Sternal Biopsy and "Buffy Coat Smears" in the Diagnosis of Aleukemic Leukoses.
- Reuben L. Kahn, D.Sc., Ann Arbor, Mich., The Question of Paradoxical Serological Reactions in Syphilis.
- Dr. Meyer Bodansky, Galveston, Texas, The Determination of Parathormone in the Blood of Pregnant Women.
- Drs. Edward C. Rosenow and Fordyce R. Heilman, Rochester, Minn., Methods of Preparation and Results from Use of Streptococcal Vaccines in the Prevention and Treatment of Respiratory Infections.
- Dr. Roy S. Leadingham, Atlanta, Rat Bite Fever: Report of Five Cases.

Neurological Meeting.—The American Neurological Association will hold its sixty-third annual convention in Atlantic City, June 3-5, under the presidency of Henry H. Donaldson, Ph.D. The speakers will include:

- Drs. Harry L. Parker and Adams A. McConnell both of Dublin, Ireland, Internal Hydrocephalus.
- Dr. Temple S. Fay, Philadelphia, Epidural Ascending Spinal Paralysis (Spiller's Syndrome).
- Dr. Louis Casamajor, New York, A Child Without a Forebrain (preliminary report).
- Dr. Smith Ely Jelliffe, New York, Sigmund Freud as a Neurologist.
- Dr. Tracy J. Putnam, Dr. Paul F. A. Hoefer and Mildred G. Gray, Ph.D., all of Boston, The Experimental Production of "Encephalomyelitis" by the Intravenous Administration of Coagulants.
- Drs. James Norman Petersen and Joseph P. Evans, both of Montreal, The Anatomical End Results of Cerebral Arterial Occlusion (An Experimental and Clinical Correlation).
- Drs. Wilder G. Penfield and Edwin B. Boldrey, both of Montreal, Somatic Motor and Sensory Representation in the Cerebral Cortex of Man as Studied by Electrical Stimulation.

American Radium Society.—The twenty-first annual meeting of the American Radium Society will be held in Atlantic City at the Chelsea Hotel, June 7-8, under the presidency of Dr. Zoe Allison Johnston, Pittsburgh. Among speakers listed are:

- Dr. Henry Schmitz, Chicago, Selection of Form of Treatment in Uterine Myomas.
- Drs. Eugene P. Pendergrass and Philip J. Hodes, Philadelphia, Observations on the Results of Treatment of Breast Carcinoma.
- Dr. Grantley W. Taylor, Boston, Artificial Menopause in Carcinoma of the Breast.
- Dr. Hugh F. Hare, Boston, Cancer of the Thyroid in Children.
- Dr. George C. Wilkins, Manchester, N. H., Methods of Applying Radium Element in the Form of Needles and Tubes.
- Andrew J. Ackerman, D.D.S., New York, Protective Shields in Radiation Therapy of Intra-Oral Cancer.
- Dr. Orville N. Meland, Los Angeles, Treatment of Epitheliomas of the Masolabial Fold.
- Drs. Harry H. Bowing and Robert E. Fricke, Rochester, Minn., Radium Therapy of Vernal Conjunctivitis.

Society News.—Dr. William J. Kerr, San Francisco, was chosen president-elect of the American College of Physicians at the annual meeting in St. Louis, April 19-23, and Dr. James H. Means, Boston, was inducted into the presidency. Vice presidents elected are Drs. David P. Barr, St. Louis; George Gill Richards, Salt Lake City, and William Gerry Morgan, Washington, D. C. The 1938 meeting will be in New York.—Dr. Charles Phillip Miller, Chicago, was elected president of the American Society for Experimental Pathology at its annual meeting in Memphis April 21-24; Dr. Morton McCutcheon, Philadelphia, vice president, and Dr. Paul R. Cannon, Chicago, secretary. The next meeting will be in Baltimore, in conjunction with the Federation of American Societies for Experimental Biology.

National Tuberculosis Association.—The thirty-third annual meeting of the National Tuberculosis Association will be at the Municipal Auditorium, Milwaukee, May 31-June 3, under the presidency of Dr. Esmond R. Long, Philadelphia. The following, among others, will present papers, according to the preliminary program:

- Drs. William H. Ordway, Mount McGregor, N. Y., and Haynes H. Fellows, New York, Fluoroscopy versus Physical Examination in the Detection of Pulmonary Tuberculosis.
- Dr. Miriam E. Bralley, Baltimore, Factors Influencing the Course of Tuberculous Infection in Young Children.
- Dr. Clarence M. Hineks, New York, The Psychotherapy of Rehabilitation of Patients in Tuberculosis Hospitals.
- Dr. Sidney J. Shipman, San Francisco, Bronchial Factor in Cavitation.
- Dr. William W. Bauer, Chicago, Measuring Health Education.
- Dr. Paul P. McCain, Sanatorium, N. C., Tuberculosis in the Negro.

Thursday, June 3, there will be a symposium on the evolution of tuberculosis dispensary control. The speakers will include Drs. Jabez H. Elliott, Toronto; Herbert R. Edwards, New York; Israel Steinberg, New York, and Henry Chesley Bush, Livermore, Calif.

Association for Thoracic Surgery.—The twentieth annual meeting of the American Association for Thoracic Surgery will be at the Hotel Saranac, Saranac Lake, N. Y., May 31-June 1. Dr. Leo Eloesser, San Francisco, will deliver his presidential address on "Bronchostenotic Cavities and Other Closed Foci of Tuberculous Suppuration in the Lung." Monday afternoon an address will be given by Prof. Hans C.

Jacobaeus, Stockholm, Sweden, entitled "Bronchospirrometry and Its Use in Determining Indications for Thoracoplasty in Bilateral Pulmonary Tuberculosis." Other speakers on the program will include:

- Dr. Gabriel Tucker, Philadelphia, Bronchoscopic Aid in the Management of Postoperative Pulmonary Complications.
- Drs. Harry C. Ballon and Alton Goldbloom, Montreal, Chemotherapy in the Treatment of Streptococcus Infections of the Pleura and Chest Wall.
- Drs. Richard H. Overholt and John S. Harter, Boston, The Lung Volume After Thoracoplasty.
- Dr. Herman J. Moersch, Rochester, Minn., Successful Treatment of Carcinoma of the Esophagus by Means of Surgical Diathermy.
- Dr. Frederick R. Harper, Tucson, Ariz., Effect of Phrenic Nerve Interruption on the Gastro-Intestinal Tract.

American Orthopedic Association.—The annual meeting of the American Orthopedic Association will be held in Lincoln, Neb., June 2 and 3 and in Omaha, June 4. Sessions in Lincoln will be at the Cornhusker Hotel and the Nebraska Orthopedic Hospital. Among the speakers will be:

- Mr. Reginald Watson-Jones, Liverpool, England, The Development of Fracture Treatment in Great Britain.
- Dr. Hiram Winnett Orr, Lincoln, Contribution of Orthopedic Surgery to the Lister Antiseptic Method.
- Dr. Dallas B. Phemister, Chicago, Experiences with Massive Bone Graft.
- Dr. Robert V. Funston, Charlottesville, Va., Dashboard Dislocations of the Hip.
- Dr. Robert B. Osgood, Boston, History of Orthopedic Surgery and the American Orthopedic Association.
- Dr. Robert C. Hood, Washington, D. C., Federal and State Care of Crippled Children.

The members will go on a special train Friday, June 4, to Omaha, where a clinical program will be presented by Drs. John P. Lord, Robert D. Schrock and their associates at the University Hospital. In the afternoon there will be a golf tournament at the Happy Hollow Country Club followed by a dinner.

Association for Study of Allergy.—The annual meeting of the Association for the Study of Allergy will be held at the Hotel Traymore, Atlantic City, June 7-8, under the presidency of Dr. Harry L. Huber, Chicago. Speakers will include:

- Drs. Richard A. Kern, Jean Crump and Rudolf L. Roddy, Philadelphia, Scarlet Fever Immunization by Intracutaneous Injection of Scarlatinal Streptococcus Toxin.
- Dr. Lewis Webb Hill, Boston, Sensitivity to House Dust and Goose Feathers in Infantile Eczema: Significance of Specific Allergens.
- Dr. Ralph H. Spangler, Philadelphia, The Leukopenic Index and Differential Counts in a Case of Gastric Ulcer.
- Drs. Elliott T. Thiene and John M. Sheldon, Ann Arbor, The Correlation of the Clinical and Pathological Findings in Bronchial Asthma.
- Dr. Salvatore J. Parlatto, Buffalo, Deficiency of Atmospheric Humidity as a Contributing Factor in Prolonged Asthma.

A round table discussion on fungi will be held Tuesday afternoon. Dr. Ernest L. MacQuiddy, Omaha, will discuss the classification; Oren C. Durham, Chicago, and Drs. Philipp Schonwald, Seattle; Samuel M. Feinberg, Chicago; Grafton Tyler Brown, Washington, D. C., the varieties of clinically important fungi found in the United States; Robert W. Lamson, Los Angeles, culturing and extraction of fungi for testing and treatment; Marion B. Sulzberger, New York, clinical manifestations of sensitivity to fungi; Harry S. Bernton, Washington, D. C., treatment, and Charles Thom, Ph.D., Washington, D. C., general remarks.

Dr. Rufus Cole Retires as Director of Rockefeller Hospital.—Dr. Rufus Cole, since 1909 director, Hospital of the Rockefeller Institute for Medical Research, has announced his retirement on account of age, effective June 30. He will be succeeded by Dr. Thomas Milton Rivers, since 1927 a member of the board of scientific directors of the International Health Division of the Rockefeller Foundation. A native of Rowsburg, Ohio, and 65 years of age, Dr. Cole took his medical degree at Johns Hopkins University School of Medicine, Baltimore, 1899. He served in various capacities at Johns Hopkins Hospital from 1899 to 1907 and at the medical school from 1901 to 1909, when he became director of the Rockefeller hospital. Dr. Cole is a member of the board of scientific directors of the International Health Division and of many national societies. He was president of the Association of American Physicians in 1931 and has been a prolific contributor to medical literature. The University of Chicago conferred the honorary degree of doctor of science on him in 1927. Dr. Rivers was born in Jonesboro, Ga., Sept. 3, 1888. He graduated from Johns Hopkins University of Medicine, Baltimore, in 1915, spending the years until 1918 on the staff of Johns Hopkins Hospital. He joined the teaching staff of the medical school in 1917, leaving in 1922 to become affiliated with the Rockefeller Institute, where he was appointed associate member in 1924 and member in 1927. Dr. Rivers was president of the American Society for Clinical Investigation in 1931 and in 1936 was awarded the honorary degree of doctor of science by Emory University, Atlanta, Ga.

Cooperation Requested in Search for Kidnapers.—The Federal Bureau of Investigation, U. S. Department of Justice, requests the cooperation of the medical profession in the apprehension of the unknown kidnaper of Charles Fletcher Mattson, 10, son of Dr. and Mrs. William W. Mattson of Tacoma, Wash. Below are reproduced two views of an artist's drawing made from oral descriptions of the kidnaper as furnished by the children who were at the home of Dr. Mattson at the time of the abduction, Dec. 27, 1936. The person who kidnaped Charles Fletcher Mattson is described as follows: age, about 30 years; height, 5 feet 7 inches; weight, 145 to 165 pounds; complexion, swarthy; spoke brokenly with slightly foreign accent; appeared to be of southern European extraction; peculiarities: did not stand erect, dimple in chin, high cheek bones, nose appeared to be broken a little below center, had hairy hands. It will be greatly appreciated if you will communicate any information you might have, or later obtain, to the nearest Division of the Federal Bureau of Investigation, U. S. Department of Justice, or to the National Headquarters of the Federal Bureau of Investigation at Washington, D. C., the telephone number of

which is National 7117. A reward of \$10,000 has been authorized by Homer S. Cummings, Attorney General of the United States, for information furnished to any representative of the Federal Bureau of Investigation leading to the identification and apprehension of the kidnaper.

Impostor Impersonates Physician.—It has been established through records of the American Medical Association that an impostor has been practicing medicine for three years in Freer, Texas, using the name of Dr. Bedford F. Floyd Jr., a physician of Memphis, Tenn. In 1935 "Dr. Floyd" was reported in Freer for the fourteenth edition of the American Medical Directory. Later that year he applied for Fellowship in the American Medical Association and was accepted by reason of his membership in the State Medical Association of Texas. Several months later it was discovered that only one Bedford F. Floyd appeared in the files of the Association and that he was a member in Tennessee. As dual membership is not allowed by the By-Laws of the Association, the Dr. Floyd at Freer was asked to explain this duplication. He replied from San Antonio that he was leaving Freer and that he would visit Memphis and clear up the confusion. Inquiry of the Memphis and Shelby County Medical Society revealed that the Dr. Bedford Forrest Floyd of Memphis had lived in Kilgore, Texas, from January 1931 to September 1933 and that he had never lived in Freer. In 1931 he reported to the American Medical Association that his diploma and Tennessee license had been lost and that duplicates were issued. These have since been recovered, he reported in September 1936. The duplicate diploma was returned to the University of Tennessee; the duplicate license was used by him to obtain his Texas license. According to the office of the Texas state board, the Dr. B. F. Floyd of Freer filed information there tallying with the credentials of the Memphis physician, including that of the lost diploma. The secretary of the Brooks-Duval-Jim Wells County Medical Society reported that when the Freer man applied for membership he gave Kilgore as his previous address and the same credentials. Previously he had used the names Earl W. Morris and Calvin Grady. The following description was given by the federal bureau of investigation: age 45, stocky build, weight 192, height 5 feet 8 inches, fair skin, blue-gray eyes, sandy or blond hair, neatly dressed, wearing diamond scarf pin and diamond ring. He has small scars on the right eyebrow and on the upper lip under the nose.

The Admission of Women Students to London Hospitals

In a letter to the *Daily Telegraph*, Professor Ryle calls attention to the fact that women are still at some educational disadvantage compared to men, especially during the clinical part of their training. The women medical students at Oxford and Cambridge are not numerous, but the three London hospitals which accept women—the Royal Free Hospital (which is entirely a medical school for women), University College Hospital and King's College Hospital—are able to find room for only a certain proportion of this group. There are in fact only twelve vacancies in London for women who have previously studied elsewhere. In the case of men, all the teaching hospitals (except the Royal Free) welcome students from Oxford and Cambridge in various ways. The contrast in opportunity becomes more pronounced when it is remembered that a considerable number of men and women are not taking University degrees at all. Some nonuniversity trained men, in fact, have all the advantages of the London teaching denied to women with honors from Oxford and Cambridge, or similarly distinguished elsewhere. University College Hospital has a competitive examination, which makes it possible for a limited number of women each year to serve there. Professor Ryle therefore asks Could not some or all of the other nine medical schools in London admit a small fixed number of women annually? He can see no reason, for instance, why Guy's, St. Bartholomew's or St. Thomas's should not encourage women from Oxford and Cambridge of good academic attainments to share the advantages accorded to the men with whom they have already worked on an equal footing for three years. If each school accepted no more than half a dozen women, the present discontent would be relieved.

Replying to this letter, *Guy's Hospital Gazette* states that there are many difficulties to prevent the adoption of Professor Ryle's proposal at Guy's, where he was a well known teacher. The pressure of students is already so great there that every effort should be made to restrict their number. The *Gazette* counters with the question, Can medicine be taught with advantage to a mixture of the sexes? The article states that many aspects of medicine would be difficult to discuss before a mixed audience—at any rate in the frank and intimate manner possible in the wards today.

Professor Ryle's letter has also given rise to correspondence in the *Lancet*. Dr. Norah H. Schuster, a pathologist, welcomes Ryle's view but points out other difficulties. The success of the London schools depends to some extent on athletic prestige, and athletes, Dr. Schuster states, hate to be educated with women. Furthermore, compared with men there is a greater risk of women failing to finish the course or to practice. But Dr. Schuster thinks that the time will come when the hospitals will realize that a superior woman may be worth more to them than an inferior man. She also suggests that the larger hospitals, which are not medical schools, may find it to their advantage to take women. To this Dr. M. E. Shaw, dean of the West London Postgraduate College, replies that the question is receiving the careful consideration of the authorities of the West London Hospital.

The Sterilization of the Unfit

In the House of Commons, Wing-Commander James called attention to the report of the Committee on Voluntary Sterilization. He moved "That the government should give further consideration to the potentialities of voluntary sterilization for

hereditary defectives in accordance with the unanimous recommendations of the Departmental Committee that reported to the Minister of Health on Jan. 8, 1934." The report stated that there were in England and Wales about 300,000 defectives, of whom 200,000 were fit for community life. At present a much smaller proportion than one third were in institutions. The departmental committee recommended that voluntary sterilization should be allowed where a person was a mental defective or had suffered from mental disorder, where a person suffered from or was believed to be a carrier of a grave physical disorder that was transmissible, and where a person was believed to be likely to transmit mental disorder or defect.

Sir A. K. Wood, minister of health, said that the question raised other matters besides health, in some quarters matters of conscience and religious conviction. The number of defectives increased as the general population increased and as the local authorities became more efficient in ascertaining the existence of defectives, but it could be said with authority that there was no proof that the incidence of mental deficiency in this country was increasing. Legislation adopted in other countries was fairly new, and no results of significance could yet be assessed. The lesson learned from happenings abroad was that the advocates of sterilization should carry public opinion with them. A great deal of research was being done in this country on the subject and there was no question that opinion was growing in favor of sterilization, but there was still much conflict of opinion, particularly on religious grounds. The medical profession was by no means unanimous on the matter. It was desirable that ample time should be given for a full consideration of the whole problem and for public opinion to develop. In view of this reply, Wing-Commander James withdrew his motion.

PARIS

Leprosy Treated at a Paris Hospital

The Hôpital Saint-Louis has one of the largest services in the world for dermatology and syphilology. It was not surprising, therefore, when a report was read at the March 16 meeting of the Académie de médecine on ninety-five cases of leprosy observed since Dec. 25, 1934, by Charles Flandin and Jean Ragu in their service at this hospital. When they took charge of the service there were only four cases, but the number has risen to twenty-six at the present time. In addition, they have had occasion to examine and follow, either at the hospital or elsewhere in Paris, sixty-nine other proved cases of leprosy. The authors gave the following reasons why so many (ninety-five) have been seen: 1. Every effort was made to use these patients as seldom as possible for teaching purposes, because they are very sensitive about their condition and resent being exhibited. 2. The patients have been assured that professional secrecy would be observed as to the nature of their ailment and that one would not insist on their being interned at this or other hospitals. 3. Such marked improvement followed the intravenous injection of a new composite of chaulmoogra oil and cholesterol (*Comptes rendus de l'Académie des sciences*, Aug. 31, 1936, p. 502), that this attracted many patients who keep well informed as to newer methods of treatment.

The report was made under three headings:

1. Contamination in the French colonies. The majority of the patients were infected in the colonies, either being born or having lived a long time there. The ninety-five cases included twenty-two natives, nine halfbreeds, seventeen white persons born in the colonies, forty-one white persons who had lived a variable length of time in the colonies, and six white persons who had never left France. The origin of the contamination was not difficult to ascertain. In all, there was a history of infection following sexual contacts.

2. Contamination during a short stay in the colonies. This group included individuals who remained a short time in regions in which either leprosy is endemic or it is rare, as in northern Africa. After a period of incubation, of only a few months in most but of years in some, the first clinical evidences appeared and the disease developed by successive exacerbations. The histories of four cases were given in which the stay in the colonies had been four, seven, eight and ten months respectively. The incubation period varied from eight months to twenty-five years. The Hansen bacilli were found in the leprous manifestations in all of these. Three were contaminated in northern Africa, where leprosy is rare except in certain portions of Morocco.

3. Contamination in France. Since 1923, when a case originating in the Parisian region was reported by Jeanselme, the authors were unable to find any case similar to six cases of their own, but they believe that it is more common than is generally supposed. Of six patients observed by Flandin and Ragu, the first had lived since birth (she is now 26 years old) in a Chinese colony in one of the Parisian suburbs; the second, a man of 50, belonged for some time to a hospital corps, during the World War, in which there were many Indo-Chinese; the remaining four had sexual relations with the leprous. The difference, according to the authors, in the incubation period (six months to twenty-five years) depends on how the patients were infected. Those simply living in a leprous environment had much longer incubation periods than those who had frequent sexual relations with the leprous. In the future, one must regard leprosy as an infection which can be found in persons who have never left France.

A Question of Money

In the February Bulletin of the Syndicate of Physicians of the Department of the Seine, in which Paris is situated, appeared an article entitled "A Question of Money." The entire profession in France is organized into syndicates or leagues, one for each of the eighty-six departments. These syndicates are quite independent of the medical societies proper, whose meetings are devoted to the reading of papers in the various branches of medicine. The syndicates are really public relations representatives of the organized profession. Each departmental syndicate has the right to appoint a certain number of its members to a central body or federation of medical syndicates of France, which receives a proportion of the annual dues of its constituent departmental syndicates. In the article referred to, the secretary of the Seine departmental syndicate, Dr. Barlerin, states that the question of how physicians here can earn enough to live is the most vital one at the beginning of 1937.

Even those who had laid aside a sum which seemed sufficient when they should be ready to retire find that, as the result of several devaluations of the franc, their income is inadequate to live on. Paris physicians are particularly hard hit. They see their professional income diminished as the result of various efforts to introduce state medicine, especially social insurance and the unrestricted admission of private patients to public hospitals and dispensaries. An additional burden is the increase in taxes imposed on all professional men, not to speak of the higher cost of maintaining a mode of life which the public expects of medical men in large cities. The Central Federation of Syndicates has asked for a 100 per cent increase of its share of the dues from members of the constituent departmental syndicates. Although this request was voted down by a large majority of the Seine syndicate, there have been a sufficient number of affirmative votes of the proposition by the syndicates of rural departments to impose the raise. This is more of a blow to physicians in larger centers than in country districts, where the members of the profession are less affected by the inroads on their income by social insurance, public hospitals and dispensaries.

New Books on the Use of Poison Gas in War

The almost simultaneous appearance of four books on the use of poison gas in war shows the importance of this question in France. A brief review of each of the books appeared in the *Presse médicale*, March 17.

In the first of the four books, on combat gas, chemical and physiologic properties, treatment and passive defense, by Capt. J. Couillaud, the preparation of every known form of toxic gas is given, as well as its properties and detection by chemical and physiologic methods. Then follows a discussion of the protection of the public as well as the organization of passive defense.

In the second book, on combat gas from the physiologic, medical and military points of view, H. Magne and D. Cordier, as physiologists, are more interested in the symptoms and physiopathology than in the chemical properties. The effects of the various forms of toxic gas on the different organs has been studied experimentally. The study of the physiology of respiration when gas masks are worn receives special attention. The methods of protection are placed in two groups: isolation and filtration.

The third book, by A. Guillaume, tells how to protect against air attacks. A detailed description is given of the methods to be adopted by civilians against the danger of air attacks. A summary follows of the various types of combat gas, the treatment of intoxications and surveillance of shelters and first aid stations.

The fourth book, by Colonel Cot, presents a course for those who have occasion to treat asphyxia in war or peace. The author has organized an excellent resuscitation service for firemen in Paris. A small amount of space is devoted to theoretical considerations of asphyxia and artificial respiration. The first part takes up the treatment of asphyxia in peace time. The second part reviews the methods usually employed for resuscitation and artificial respiration, especially the use of carbon dioxide-oxygen mixture and the author's own method of artificial respiration, which has proved to be efficacious here. The third part describes asphyxias in war, as in the first three books.

BERLIN

(From Our Regular Correspondent)

April 21, 1937.

Increase in Physical Endurance Through Alkalization

Professor Dennig, director of one of the clinics of internal medicine at Berlin University, has studied the interrelation of acids and physical exertion and reported his observations to the Berlin Medical Society. The tests carried out took as their point of departure the fact that work leads to the formation of acids. Previously it has been observed that early exhaustion can be induced by an artificial acidulation. Dennig attempted to demonstrate the converse; namely, that by alkalization of the organism an increased capability can be obtained. He found that recuperation did actually take place more rapidly and that physical labor could be performed over a longer period. Ten persons were subjected to the tests, which were by no means uniform. By a careful arrangement of the tests, errors that could be due to suggestion were avoided. The length of time during which exercise on a treadmill could be maintained was raised under alkalosis to forty-two minutes, whereas previously the subject was completely exhausted after twenty minutes. This favorable effect of alkalosis depends, as Dennig found, on various factors. As a result of the increased arterial carbon dioxide pressure during work the respiratory volume declines, causing a slackening of performance and the sensation of dyspnea. The acidosis produced during work in the main by lactic acid was less, because better neutralized by the previous alkalization. As there is diminished hydrogen ion concentration, the brain and musculature are protected and fatigue is warded off. In addition, quick relaxation follows the suspension of work. After thorough investigation of the manner in

which the optimal artificial alkalosis may be obtained, the substances observed to be most favorable were sodium citrate, sodium bicarbonate and potassium citrate taken twice daily as postprandial powders. If secondary manifestations, diarrhea for example, appear then the dosage should be reduced. The optimal effect is obtained after two or three days. None of the powders ought to be taken within five hours preceding the work. This artificial alkalization must not be carried on for longer than three or four days at a time. After an interval of several days it may be resumed. To avoid a reaction of acidosis, the dosage is decreased gradually before the powder is discontinued. In overdosage there is danger of tetany, but if this condition appears it can be relieved in a few minutes by administration of ammonium chloride. Artificial alkalosis is in some respects the equivalent of a most rigorous training, for in the latter condition there will also be an increase of carbon dioxide pressure in the alveoli which frequently borders on tetany. Alkalosis can also be brought about by a uniform diet (milk, potatoes, vegetables) but this never reaches the level of a medically produced condition. Only soy meal, a food of marked alkalotic properties, if ingested in large quantities (of around 300 Gm.) will induce a condition in any way comparable to alkalosis by medication. Before practical application of these observations is made it will be necessary to make supplementary examinations of various physical phenomena. For example, it is yet to be determined how artificial alkalosis acts if work is continued over longer periods.

Death of Prof. Robert Sommer

The Giessen psychiatrist Robert Sommer, M.D., Ph.D., died February 2 of pneumonia at the age of 72. With him passes one of the original leaders and many-sided innovators in the domain of psychiatry and related specialties. A pupil of Wundt, Sommer became ordinarius in psychiatry at Giessen when only 30 years of age. His work was consistently characterized not only by the zeal for experimental research but by great philosophic and intellectual insight as well. Sommer interested himself in many aspects of his specialty: psychology and esthetics, examination methods of psychopathology, eugenics and study of the family, animal psychology and so on. An especially interesting treatise discussed war and psychic conditions. Sommer early recognized the significance of hereditary factors. In 1925 he organized the German Association of Mental Hygiene, which together with the German Society of Psychotherapy also founded by him had as its objective the waging of a practical campaign against the dangers of mental and nervous diseases.

Tularemia in Austria

For about eighteen months there have been observed in Austria isolated cases of the disease first recognized in North America and known as tularemia. Several cases of the ulcerous-glandular variety, a type never before encountered in this country, were recently reported to the Vienna Physicians' Society. Prof. Dr. Kerl had the opportunity to observe a case in which a peasant, aged 51, shot a hare and while drawing the animal cut himself. Subsequently he was stricken with a disorder resembling influenza. Several other peasants of the same region also came down with the same sort of malady and in each case there was a history of a lesion sustained while handling hares. The first case was correctly diagnosed only when a hematogenic examination for tularemia showed positive agglutination. Thereupon treatment of all the other sick men was begun. Most striking was the massive swelling of the axillary lymph glands, whereas only small ulcerations appeared on the fingers and forearm. For the intracutaneous diagnostic test a suitable dilution (1:100 and 1:1,000) is necessary.

Furthermore, Dr. Bsteh has reported a small epidemic of tularemia in a rural district not far from Vienna. There were thirty-four cases, one of which was fatal. It was possible to differentiate several types: the ulcerous-glandular, the ocular, the pulmonary and, in addition, a new anginal type. The last-named began like an influenza, with acute tonsillitis and severe swelling of the cervical glands. Resolution rapidly took place. The incubation period of the disease was from eight hours to eight days. The onset was turbulent and marked by remittent fever. Curiously, a short while prior to this epidemic the district in question had been infested with incredible numbers of field mice. Examination of the viscera in a fatal case of tularemia disclosed that the lungs were normal excepting for congestion; there were degenerative changes in the liver, pus in the axillary lymph nodes and the spleen, and numerous small nodular infiltrations in which resolution was already at hand. *Endothelioid cells and giant polymorphonuclears* were also observed. Streak preparation showed no micro-organisms and no acid-fast rods, a condition that has previously been noted in the literature. There was no eosinophilia but marked leukocytosis.

Prof. Dr. David of the Vienna School of Veterinary Medicine also reported his own studies of tularemia. It was he who with Dr. Pilot described (March 10, 1936) the first case of the disease ever reported in Austria. He believes, however, that for the past twenty years at least there have been cases of tularemia in this country that were not diagnosed as such. The disease is extremely infectious; in spite of all precautions (rubber masks, rubber gloves and rubber gowns) a laboratory infection was reported in Vienna. Whereas in America some 6,000 cases have been reported to date, in Austria only about 200 cases have been recognized and most of these within the last four months. How animals become infected is not clearly understood; flies and ticks probably play an important part as hosts. A majority of the Austrian patients were men, chiefly hunters, dealers in game and pelters. Cases were, however, reported among housewives and other women who had come into contact with diseased rabbits.

Interesting is the observation that the agglutinin content in the blood serum of a tularemia patient will remain abnormally high for years, perhaps for life; the maximal value is reached between the sixth and the eighth week of illness and there is a subsequent decline. Professor David recommends that tularemia be made a reportable disease and that rigorous measures be taken to prevent its transmission.

Wagner-Jauregg Honored on Eightieth Birthday

A few days ago the eightieth birthday of Prof. Julius Wagner-Jauregg was celebrated by a great number of high officials and scientific bodies. The man so honored was the discoverer of the use of malariotherapy in dementia paralytica as well as the initiator of general iodine prophylaxis of cretinism and goiter. The Austrian Society of Neurology and Psychiatry held a special session at Vienna in honor of the occasion. Almost every person of prominence in Austria attended. Professor Pötzl, who succeeded Professor Wagner-Jauregg as head of the clinic, paid appropriate tribute to the achievements of his illustrious predecessor. Fifty years ago Wagner-Jauregg conceived the idea of combating syphilitic infections with artificial hyperpyrexia. This idea resulted from the observation of an insane woman who, after the subsidence of a hyperpyrexial erysipelas, appeared virtually cured. After thirty years of systematic research and testing of various methods of inducing fever in paralytic patients (hot baths, inoculation with the virus of typhoid, recurrent fever, malaria and with tuberculin), he was able finally to bring his malariotherapeutic method to perfection and in 1917 he demonstrated before the Vienna Physicians' Society two patients who had been completely cured of dementia paralytica by the use of this method. His discovery

was the result of profound observation and research. Two pupils of Wagner-Jauregg, Hoff and Silberstein, were subsequently the first to prove that the antisiphilitic defense forces of the organism wax more powerful in direct proportion to the strength of the malarial infection. Malaria bears a similar relation to all other types of bacterial infection. It is an interesting fact that the original stock of *Plasmodium malariae* which was placed at Wagner-Jauregg's disposal in 1917 by Professor Doerr for experimental purposes still remains lively and active after 481 person to person transfers. Moreover, studies of and experimentation with this stock culture of the plasmodium have been responsible for valuable contributions to scientific knowledge.

Wagner-Jauregg will also be remembered as the initiator of goiter prophylaxis in the Alpine regions of Austria. It was he who recommended the admixture of a small amount of potassium iodide to the common kitchen salt (about 1 mg. per kilogram of salt), so that every one in Austria is compelled to use iodized salt, and iodine free salt is to be only had under special circumstances. The results of this general administration of iodide to an entire nation have been most gratifying and they are the object of a painstaking survey undertaken by Wagner-Jauregg himself, assisted by Hausmann. The data gleaned from this survey have only just been published (*Mitteilungen des Volksgesundheitsamtes*, Vienna, 1937, No. 3). It is reported therein, for example, how in a certain mountainous region of Austria, regarded as a typical goiter zone, fully developed goiter among the school children practically disappeared after a sixteen year period during which the population used only iodized salt. Severe goiter had previously been present in 4 per thousand of the school population. In the same sixteen years there was also a 90 per cent decrease in cases of "blähals" (slight enlargement of the thyroid).

Professor Wagner-Jauregg was awarded the Nobel prize in 1927. It has been decided that the Vienna Neurologic Clinic shall henceforth and forevermore be known as the "Wagner-Jauregg Clinic" and, moreover, the special commemorative gold medal that was struck in honor of the neurologist has been made the property of the clinic. It is characteristic of his lifelong aversion to "publicity" that he saw fit to avoid the recent festivities held in his honor.

BELGIUM

Creation of an Order of Physicians

In accordance with a resolution passed by the twenty-eighth Congress of Professional Medicine, held at Liège last July, the Executive Committee of the *Fédération Médicale Belge* appointed a commission representing the various specialties. This commission was empowered to frame appropriate legislation for the creation of an "Ordre des médecins" (order of physicians). This order as contemplated will act as an official guardian and arbiter of medical ethics. It will have no opportunity to abuse its authority either by the slightest coercion of any physician in any manner whatever or by the least restriction of legitimate professional prerogatives. An outline of the proposed legislation follows:

An Ordre des médecins is hereby created in Belgium. Its status is that of a civil body. The Ordre des médecins includes in its membership all doctors of medicine, surgery and obstetrics resident in Belgium who are regularly licensed to practice the art of healing. The various councils within the order see to it that all members show a proper respect for the professional traditions of dignity, delicacy and integrity. The councils also serve to defend the honor of the medical profession. The councils are forbidden to interfere in religious, philosophical, political, linguistic and syndical controversies.

The councils are not authorized to regulate the amount of physicians' honorariums or the manner in which these shall be charged, excepting in case of a habitual exaction of exorbitant fees which goes so far as to constitute a breach of professional probity.

The members of the councils, both officers and associates, are elected for a term of four years from among physicians of Belgian nationality who are at least 35 years of age, who have held licenses to practice medicine for at least five years previous to election, and who reside in the provinces.

No member can be reelected for more than one additional consecutive term. The terms of one half of a council's membership will expire at the end of each two years. At the first election one half of the members shall be elected to serve four years, the remainder to serve two years. Each council of the order elects its officers—a president, vice president and secretary—from among its membership.

Each council of the order is assisted in an advisory capacity by the magistrate of a court of first instance who is an appointee of the crown.

There is a superior council, which numbers among its duties the pronouncement of reasoned opinions on questions of a general nature and the collation of the opinions of the various lower councils, all with a view to the establishment of a body of deontologic jurisprudence.

A council of the order is empowered to invoke the following sanctions: admonition, censure, reprimand, suspension from medical practice for not longer than one year, and absolute prohibition from practicing medicine in Belgium. A physician who has been suspended automatically loses his membership in any council and if under temporary suspension he forfeits his right to vote during the period of suspension.

The foregoing sanctions can be invoked thirty days after the accused physician has been summoned to defend himself before the proper disciplinary tribunal. He is permitted to call on one or more of the councils to assist in his defense.

The same rules are followed by the superior council. For suspension or expulsion of a member, a majority vote of two thirds of the council members present is required.

The president of a council of the order, the advisory magistrate and the interested parties may take an appeal from any decision of the council.

The provincial medical committee is apprised of all final sentences of suspension or expulsion.

The record of any disciplinary action must be accompanied by a full statement of the motivating circumstances.

Members of the councils of the order, of the superior council and of the mixed appellate committees are bound to professional secrecy with regard to all matters of which they have ex-official knowledge.

Belgian Congress of Psychiatry

At the opening session of the Belgian Congress of Psychiatry, Minister of Health Vandervelde explained the revised law for the treatment of the insane. The spirit of the new law would tend to integrate the welfare of the mental patient into the system of general welfare. The organized service should be based on (a) an alert medical inspection service possessed of adequate official powers, (b) independent observation units staffed by a competent personnel trained in the most modern technics of investigation, and (c) great flexibility with regard to the admission, release or maintenance of a patient at the Psychiatric Institute. All this assumes a greater confidence on the part of the public authorities and of the public in the physician's understanding of his duty to society. The new legislation would seem to foster the development of unclassified sections for patients whose internment is not legally compulsory.

Among the papers read, that of Rouvroy on "Experimental Studies of the Intelligence of Mental Patients" is particularly

worthy of mention. Most writers who have studied this problem have based their observations on standards established by pedagogic psychology. Rouvroy believes that this approach is faulty on practical application. At the beginning of a psychic disturbance, the old tests reveal most frequently a complete integrity of automatized aptitudes. In this phenomenon lies a source of error, since the tests designed for pedagogic purposes consider as equal values true intelligence and old automatisms. The results, as expressed grossly by a "mental age" or a single figure, fail to represent the actual level of intelligence. It is therefore necessary to differentiate automatic and intellectual action and to make separate evaluations of each. This method represents an advance in that it provides an opportunity for objective evaluation of the patient's intellectual level before the onset of the disturbance.

TREATMENT OF MENTAL DISEQUILIBRIUM ACCOMPANIED BY ANTISOCIAL REACTIONS

Louis Vervaeck reviewed the favorable observations in the first quinquennial report on the extension of the law of social defense to persons of abnormal mentality. Of 1,072 patients conditionally released from psychopathic institutions, 256 (23 per cent) were reinterned. Only 122 (11 per cent) of the latter group were criminal recidivists. The other 113 were reinterned because of inability to adapt themselves to the living conditions arranged for them on the outside; either the mental condition had, according to a psychiatrist's report, become further aggravated or the patients had asked to be returned to an institution of social defense. Dr. Vervaeck outlined the therapeutic measures that seem to him indicated in mental cases that are accompanied by antisocial tendencies. He stressed the value of training the will power and the moral sense, readaptation to a social existence under moral guidance and regular psychiatric control, in a favorable environment.

ARTHRITIS AND ARTHROPATHIES IN NEUROSYPHILIS

Dujardin and Friart exhibited several photographs of syphilitic arthropathies and tabetic osteo-arthropathies with fractures. The pictures were accompanied by a complete study of the reactions in the blood and cerebrospinal fluid in each case. These studies show that the cerebrospinal fluid syndrome disappears on the first day; the hematologic syndrome then disappears at the same rate as the generalized chronic inflammatory manifestations.

ITALY

(From Our Regular Correspondent)

April 15, 1937.

Influenza Epidemic

The Department of Public Health recently held a meeting with Drs. Di Blasi, Frugoni, Morelli and Caronia, all of the University of Rome, to discuss ways and means for controlling the influenza epidemic that is now flourishing in Italy. Rome, with a population of 1,200,000, had an average daily mortality of sixty-one deaths during the last month, eighteen of which resulted from bronchopulmonary diseases. In Milan, with 1,000,000 inhabitants, there were 809 deaths during the last fortnight, 303 of which were caused by bronchopulmonary diseases. In some important cities of different provinces the epidemic is widespread, but the nature of the disease is benign. Complications follow only in the elderly and the mortality rate is low. According to the members of this conference, the evolution of the epidemics does not demand special preventive measures, aside from those already being taken, for controlling the disease.

The Antivenereal Crusade

Statistics on the frequency of venereal diseases in Italy were presented to the Congress of Dermatology and Syphilography recently at Rome. New regulations were promulgated by the Department of Public Health for intensifying the crusade

against venereal diseases. The support given by the government to antivenereal dispensaries will be more substantial than at present. Whenever the personnel of antivenereal dispensaries is not able to carry on serologic, microscopic and laboratory work for diagnostic purposes, the tests will be made without charge at the laboratories of hygiene and public health of the city. The care of the patients at the dispensaries will be given free, regardless of the economic conditions of the patients. Increased use of propaganda for educating the people in antivenereal problems will be an added duty of dispensary personnel. This will be done both by instructing the patients during clinical consultations and by circulation of literature. Municipal physicians must attend courses on the subject, which will be given at the dermatologic clinics of the universities.

Invisible Dermatoses

Dr. Montesano, in a recent issue of *Attualità medica*, reported studies on certain dermatoses that exist for some time before showing themselves on the skin. Cutaneous atrophy appears late in the evolution of syphilis in certain areas of the skin that never before were the seat of syphiloderma. Brocq's pseudo-area of atrophy and alopecia, which develops late in follicular and perifollicular pathologic conditions, and lichenification are also forms of invisible dermatoses. Existence of the latter is manifested sometimes by the presence of pruritus or the appearance of leukoderma following exposure of the skin to the sun. The study of this group of dermatoses is of importance because it is concerned with disorders of the skin in their relation with the organism as a whole. The skin forms a complete system which reacts as a unit to the disturbance of any of its constituents or appendages. The rôle of the skin in the production of immunity and its relation with all organic systems show that the skin lesion is but an aspect of a disease the causal factors of which may be located elsewhere in the organism. The skin is concerned with important functions and reactions. It has been called the "peripheral brain." The study of invisible dermatoses, also called cryptodermatoses, may result in solving several problems of practical and scientific value.

Deaths

Prof. Alberto Lutrario, for the last twelve years head of the department of public health in Italy, died recently. During his administration many improvements in the general hygiene of the city, the establishment of a potable water supply, public baths, new sewer systems and other public commodities and means for the prevention of diseases and of epidemics were made. He was given the gold medal with which men are honored for meritorious work in public health.

Dr. Olimpio Cozzolino, professor of pediatrics at the Bari University, also died recently. He published several articles reporting work performed on the thymus, infantile tuberculosis, rickets, spasmophilia and Barlow's disease. His textbook on pediatrics, the first edition of which was published not long ago, is already in the third edition.

Marriages

NATHAN ANTHONY WOMACK, St. Louis, to Miss Margaret Elizabeth Richardson at Reidsville, N. C., January 23.

WILLIAM ROSARIO FERRARO, Canton, Ohio, to Miss Mary Rose Freschi of Brooklyn, January 9.

ALDWIN GEORGE FUNDERBURK, Moultrie, Ga., to Miss Louise Canipe in Folkston, January 3.

JOHN H. MATHESON to Miss Helen Lucille Baker, both of Des Moines, Iowa, May 21.

GORDON N. BEST to Mrs. Ann Jennings, both of Council Bluffs, Iowa, April 16.

Deaths

Reginald Knight Smith, died at his home in San Francisco, April 18, of coronary occlusion, aged 67. Dr. Smith was born in Newberg, Ala., Sept. 22, 1869. He received the medical degree from the College of Physicians and Surgeons in Baltimore in 1892; later served in the Medical Corps of the U. S. Navy, where he was a lieutenant commander during the Spanish-American War. He had practiced in San Francisco since 1903, and specialized chiefly in obstetrics. His early experience was in the Emanuel Sisterhood Polyclinic and the Fruit and Flower Mission, then in the Mount Zion obstetrical clinic, where in 1910 he became chief. He was instructor in obstetrics at Cooper Medical College during 1908-1909 and later assistant clinical professor of obstetrics at the University of California Medical School. Dr. Smith was a member of the California Medical Association and of the Pacific Coast Society of Obstetrics and Gynecology; a past president of the San Francisco County Medical Society and of the California Academy of Medicine.

Eugene Franklin McCampbell, Columbus, Ohio; Rush Medical College, Chicago, 1912; dean, 1916-1927, professor of preventive medicine, 1913-1927, professor of bacteriology, 1910-1913, associate professor of bacteriology, 1908-1910, and instructor of bacteriology, 1906-1908, Ohio State University College of Medicine; instructor of bacteriology at the Ohio Medical University, 1903-1904; assistant in pathology at the University of Chicago during the summers of 1908-1911; assistant in bacteriology at the University of Wisconsin, 1905-1906; secretary and executive officer of the Ohio State Board of Health, 1912-1916; pathologist to the Columbus State Hospital, 1909-1911; served during the World War; president of the Columbus Academy of Medicine; fellow of the American College of Physicians; member of the staffs of the Grant, Mount Carmel and White Cross hospitals; co-author of "General Bacteriology"; and author of "Laboratory Methods for Study of Immunity"; aged 55; died, May 8, of pneumonia.

James Newell Vander Veer, Albany, N. Y.; Albany Medical College, 1903; member of the House of Delegates of the American Medical Association, 1926-1935; past president of the Medical Society of the State of New York and the Medical Society of the County of Albany; formerly clinical professor of genito-urinary surgery at his alma mater; member of the American Urological Association; fellow of the American College of Surgeons; served during the World War; consulting genito-urinary surgeon to the Memorial Hospital, Albany, Memorial Hospital, Catskill, Mary McClellan Hospital, Cambridge, and the Moses-Ludington Hospital, Ticonderoga; aged 59; died, May 15, of heart disease.

Benjamin Hobson Frayser, Lexington, Ky.; Tennessee Medical College, Knoxville, 1909; formerly associate professor of obstetrics and instructor in anatomy at Lincoln Memorial University Medical Department, and associate professor at the University of the South Medical Department, Sewanee, Tenn.; was commissioned in the medical reserve corps of the U. S. Army and the U. S. Public Health Service; was chief of the medical and surgical services of the Veterans Administration Facility; retired because of physical disability, Jan. 1, 1937; fellow of the American College of Physicians; aged 49; died, March 5, of carcinoma of the descending colon.

Gilbert Langdon Bailey, Lexington, Ky.; Miami Medical College, Cincinnati, 1893; also a lawyer; instructor in various branches at his alma mater, 1897-1905; served as a director of a hospital in Germany during the World War; at one time clinical instructor in orthopedic surgery, College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois; for eight years chairman of the county school board; at one time on the staff of the Oak Park (Ill.) Hospital; orthopedic surgeon to the Cook County Hospital, Chicago, 1908-1912; aged 65; died, March 5, in St. Joseph's Hospital, of coronary occlusion.

William Gammon, Galveston, Texas; University of Texas School of Medicine, Galveston, 1893; formerly associate professor of pediatrics and medicine at his alma mater and at various times demonstrator of pathology, associate in pathology, lecturer in medical jurisprudence and lecturer in dermatology; veteran of the Spanish-American War; fellow of the American College of Surgeons; superintendent of the John Sealy Hospital, 1894 to 1896; surgeon to St. Mary's Infirmary; aged 65; died, March 9, of bronchopneumonia.

Charles Chauncey Duryee, Schenectady, N. Y.; Albany (N. Y.) Medical College, 1881; in 1892 president of the Medical Society of the County of Schenectady; mayor of Schenectady.

1898-1899 and 1910-1911; formerly health officer of Schenectady, member of the state board for criminals and feeble-minded, and sanitary supervisor of the state department of health; at various times consulting surgeon and consulting physician to the Ellis Hospital; aged 78; died, March 18, of diabetes mellitus and cerebral thrombosis.

Henry Allison Ingalls • Roswell, N. M.; University of Texas School of Medicine, Galveston, 1898; past president of the New Mexico Medical Society and of the Chaves County Medical Society; veteran of the Spanish-American and World wars; fellow of the American College of Surgeons; professor of military hygiene, New Mexico Military Institute; visiting surgeon to St. Mary's Hospital; aged 68; died, March 29.

Irving Herbert Eddy • Glendale, Calif.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1903; at one time instructor in gynecology at his alma mater and associate professor of gynecology at the Loyola University School of Medicine; associate in gynecology at the Chicago College of Medicine and Surgery, 1915-1917; aged 59; hanged himself, March 1.

Samuel Berardelli, Weirton, W. Va.; Loyola University School of Medicine, Chicago, 1926; member of the West Virginia State Medical Association; secretary-treasurer of the Hancock County Medical Society; past president of the board of education; aged 35; died, March 3, in the Eye and Ear Hospital, Pittsburgh, of arteriosclerosis and chronic nephritis.

Herman Jarecky, New York; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1886; member of the Medical Society of the State of New York, and the American Academy of Ophthalmology and Oto-Laryngology; consulting otorhinolaryngologist to the Sydenham Hospital; aged 73; died, March 14, in a local hospital.

Walter James Clarke, New York; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1889; member of the Medical Society of the State of New York; on the staff of the American Social Hygiene Association; aged 72; died suddenly, March 8, of coronary thrombosis.

Edith Esty Woodill, Waltham, Mass.; Tufts College Medical School, Boston, 1904; member of the Massachusetts Medical Society and the New England Society of Psychiatry; on the staff of the Walter E. Fernald State School; died, February 27, in Brookline, of carcinoma of the sigmoid with metastasis to the liver.

Rollin Hills • Brooklyn; Cornell University Medical College, New York, 1905; was chief of the tuberculosis bureau of the board of health for the Bay Ridge section; on the staffs of the Norwegian-Lutheran Deaconesses' Home and Hospital and the Victory Memorial Hospital; aged 53; was found dead, March 14.

Alfred Stocker, Rock Island, Ill.; Barnes Medical College, St. Louis, 1900; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1904; served during the World War; aged 67; died, March 20, in St. Anthony's Hospital, of coronary thrombosis.

Norman Clarence Williams, Bandelier, N. M.; University of Toronto Faculty of Medicine, Toronto, Ont., Canada, 1898; member of the Colorado State Medical Society; formerly a practitioner in Denver and Florence, Colo.; aged 61; died, February 3, in Santa Fe, of acute nephritis.

Charles Henry Clifford, Braddock, Pa.; Jefferson Medical College of Philadelphia, 1887; member of the Medical Society of the State of Pennsylvania; school physician, and member of the board of health of North Braddock; aged 75; died, March 1, of chronic nephritis and uremia.

Ramey M. Baker • Sturgis, S. D.; University of Nebraska College of Medicine, Omaha, 1931; president and formerly secretary of the Black Hills District Medical Society; aged 30; died, March 2, in a hospital at Rapid City, of streptococcal septicemia, pneumonia and cellulitis.

Frank Hinchman Clark, Brooklyn; Long Island College Hospital, Brooklyn, 1887; aged 75; on the staff of the Adelphi Hospital and on the courtesy staff of the Prospect Heights Hospital, where he died, March 3, of hypertrophy of the prostate and chronic myocarditis.

Elmer Ellsworth Ellis, Brookfield, Vt.; University of Vermont College of Medicine, Burlington, 1895; member of the Vermont State Medical Society; formerly state senator; for many years health officer and school director; aged 71; died, March 6, of heart disease.

William B. Stokes, Farmington, Ky.; University of Louisville Medical Department, 1890; member of the Kentucky State

Medical Association; past president of the Graves County Medical Society; aged 75; died, February 27, in the Mayfield (Ky.) Hospital, of pneumonia.

Jesse S. Coontz, Leon, Iowa; Keokuk Medical College, College of Physicians and Surgeons, 1903; member of the Iowa State Medical Society; past president and secretary of the Decatur County Medical Society; aged 61; died, February 28, of malignant lymphoma.

Andrew Fay Currier, Cheshire, Conn.; Yale University School of Medicine, New Haven, 1880; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1881; aged 85; died, March 4, of septicemia and hypertrophy of the prostate.

James Wilmot Lawrence • Malden, Mass.; McGill University Faculty of Medicine, Montreal, Que., Canada, 1893; on the staff of the Malden Hospital; aged 74; died, March 4, of heart disease while aboard ship homeward bound from a vacation in Jamaica.

Rosina Rehner Wistein, Cedar Rapids, Iowa; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1904; member of the Iowa State Medical Society; aged 69; died, February 23, of diabetes mellitus and chronic nephritis.

John Augustus Robert Moseley, Jefferson, Texas; Memphis (Tenn.) Hospital Medical College, 1892; member of the State Medical Association of Texas; president of the Cass-Marion Counties Medical Society; aged 68; died, February 26, of myocarditis.

Charles J. Kneer, Oaklandon, Ind.; Medical College of Indiana, Indianapolis, 1901; member of the Indiana State Medical Association; on the staff of the Methodist Episcopal Hospital, Indianapolis; aged 61; died, March 3, of cardiovascular renal disease.

Edward H. Salmon, Jersey City, N. J.; Baltimore Medical College, 1907; member of the Medical Society of New Jersey; for many years chief of the division of communicable diseases of the city health department; aged 61; died, February 28, of epithelioma.

Martin Leo Connors, Pittston, Pa.; Temple University School of Medicine, Philadelphia, 1919; served during the World War; formerly medical examiner for the city schools; on the staff of the Pittston Hospital; aged 45; was found dead, March 9.

James D. Schmied, New Martinsville, W. Va.; College of Physicians and Surgeons, Baltimore, 1892; formerly mayor; served during the World War; on the staff of the Wetzel County Hospital; aged 67; died, February 24, of cerebral hemorrhage.

Harris Alonzo Bolton • Warm Springs, Mont.; College of Physicians and Surgeons, Baltimore, 1910; member of the American Psychiatric Association; medical superintendent of the Montana State Hospital; aged 53; died, March 17, of pneumonia.

Jesse Robert Haley, Brookfield, Mo.; University of Kansas School of Medicine, Kansas City, 1926; member of the Missouri State Medical Association; aged 35; died, February 14, in a hospital at Kansas City, of streptococcus septicemia.

Emery Oliver Starling Brown, Lorain, Ohio; Starling Medical College, Columbus, 1890; member of the Ohio State Medical Association; aged 67; for many years on the staff of St. Joseph's Hospital, where he died, March 4, of pneumonia.

William Thomas Williams, Natchitoches, La.; University of Louisiana Medical Department, New Orleans, 1882; past president of the city board of health and city physician; aged 78; died, February 17, of heart disease and arteriosclerosis.

Allen Lincoln Walton, Upper Sandusky, Ohio; Starling Medical College, Columbus, 1896; member of the Ohio State Medical Association; formerly member of the state legislature; aged 73; died, February 28, of influenza and pneumonia.

Agnes Douglas Craine, Smiths Falls, Ont., Canada; Queen's University Faculty of Medicine, Kingston, 1888; L.R.C.S., Edinburgh, 1889, L.R.C.P., Edinburgh, 1889 and L.F.P.S., Glasgow, 1889; aged 75; died, February 26.

Edward Vincent Colbert, Albany, N. Y.; Albany Medical College, 1890; member of the Medical Society of the State of New York; for many years medical examiner for the army and navy recruits; aged 70; died, March 2, of pneumonia.

Irvin M. Wertz, Hagerstown, Md.; Baltimore Medical College, 1903; member of the Medical and Chirurgical Faculty of Maryland; mayor of Hagerstown; on the staff of the Washington County Hospital; aged 64; died, February 23.

James Mullins Grantham © Tampa, Fla.; Baltimore Medical College, 1898; formerly health officer of Tampa; aged 63; on the staffs of St. Joseph's and the Municipal Hospital, where he died, February 26, of a cerebral hemorrhage.

Ralph Cambren Henderson © Erie, Kan.; Kansas City Medical College, 1899; University of Kansas School of Medicine, Kansas City, 1906; served during the World War; aged 61; died, February 17, of acute myocarditis.

Thomas D. Shotts, San Angelo, Texas; Atlanta Medical College, 1915; member of the State Medical Association of Texas; medical director of the San Angelo Sanatorium; aged 48; died, February 21, of heart disease.

Frederick A. Churchill, Seattle; Chicago Homeopathic Medical College, 1882; formerly member of the city board of health, and board of education; aged 80; died, March 5, in the Maynard Hospital, of bronchial asthma.

Ira Daniel Hasbrouck, Washington, R. I.; Albany (N. Y.) Medical College, 1896; member of the Rhode Island Medical Society; township health officer; school medical inspector; aged 72; died, March 2, of pneumonia.

Marion Marsh, Muskegon, Mich.; Woman's Medical College of the New York Infirmary for Women and Children, New York, 1895; aged 80; died, February 21, in the Hackley Hospital, of cerebral hemorrhage.

Conrad Emil Thomas, St. Joseph, Mo.; Keokuk (Iowa) Medical College, 1891; member of the Missouri State Medical Association; aged 69; died, February 26, in the Missouri Methodist Hospital, of pneumonia.

Isaac Kingsley Givens, Norfolk, Va.; Howard University College of Medicine, Washington, D. C., 1931; aged 29; died, February 9, in the Jeanes Hospital, Philadelphia, of osteogenic sarcoma of the cranial bones.

Warren V. Philbrick, Worcester, Mass.; College of Physicians and Surgeons, Baltimore, 1885; aged 87; died, March 31, in St. Vincent's Hospital, of injuries received when he was struck by an automobile.

George Leander Bayton, Philadelphia; Howard University College of Medicine, Washington, D. C., 1906; member of the Medical Society of the State of Pennsylvania; aged 59; died, March 4, of pneumonia.

Irvin Phillips, Picher, Okla.; Beaumont Hospital Medical College, St. Louis, 1887; member of the Oklahoma State Medical Association; aged 79; died, February 27, near Buffalo, Mo., of cerebral hemorrhage.

Walter Taylor Miller, Fort Payne, Ala.; Birmingham Medical College, 1907; member of the Medical Association of the State of Alabama; aged 52; died, February 27, of pulmonary tuberculosis.

Harold Altin Winter, Houston, Texas; University of Tennessee College of Medicine, Memphis, 1917; aged 44; was killed, February 22, when the automobile in which he was driving was struck by a train.

Joseph Edgar Bates, Toronto, Ont., Canada; University of Toronto Faculty of Medicine, 1922; member of the American Association of Pathologists and Bacteriologists; aged 41; died, February 21.

Samuel L. Laswell, Alma, Ill.; Central College of Physicians and Surgeons, Indianapolis, 1898; member of the Illinois State Medical Society; aged 62; died, February 26, of cerebral hemorrhage.

Stanton Albert McCool, Seneca, Kan.; Ensworth Medical College, St. Joseph, Mo., 1908; member of the Kansas Medical Society; aged 54; was killed, February 6, in an automobile accident.

Noah Jefferson Goshorn, Washington, Ind.; Medical College of Ohio, Cincinnati, 1874; aged 88; died, March 31, in the Davies County Hospital, of injuries received in an automobile accident.

Alexander Hamilton Brown, Little Rock, Ark.; Illinois Medical College, Chicago, 1904; aged 62; died, March 1, in the United Friends Hospital, of a bullet wound inflicted by a burglar.

Edward Bridges, Sonestown, Pa.; Jefferson Medical College of Philadelphia, 1929; member of the Medical Society of the State of Pennsylvania; aged 35; died, March 1, of pneumonia.

Wray Adla Yoder, Buffalo, Wyo.; University of Nebraska College of Medicine, Omaha, 1929; aged 36; died, February 19, in the Sheridan County Memorial Hospital, Sheridan, of scarlet fever.

Willard Curtis Rank, Newark, Ohio; Miami Medical College, Cincinnati, 1892; formerly health officer and member of the board of education; aged 77; died, February 20, of influenza.

John Ellsworth Smith, Kansas City, Kan.; Medico-Chirurgical College of Kansas City, 1899; served during the World War; aged 68; died, February 22, of cerebral arteriosclerosis.

Adalbert Fenyes, Pasadena, Calif.; Medizinische Fakultät der Universität Wien, Austria, 1889; aged 74; died, February 22, of carcinoma of the tongue and cheek and cervical glands.

Reilly J. Alcorn, Grand Coulee, Wash.; Central Medical College of St. Joseph, Mo., 1898; also a druggist; aged 68; died, February 21, in Los Angeles, of cerebral thrombosis.

William A. Hampton, Denver; College of Physicians and Surgeons, Keokuk, Iowa, 1877; aged 87; died, February 6, of arteriosclerosis, bronchopneumonia and chronic prostatitis.

Eli H. Bradford, Rock Island, Ill.; Chicago Homeopathic Medical College, 1886; member of the Illinois State Medical Society; aged 75; died, March 3, of cardiorenal disease.

Lewis E. Clark, Mansfield, Ill. (licensed in Illinois in 1889); aged 90; died, March 5, in the Mercy Hospital, Urbana, of an embolism, resulting from a hip fracture received in a fall.

Harry W. Uffelman © York, Pa.; College of Physicians and Surgeons, Baltimore, 1907; aged 53; was found shot and killed, February 5, on the desert outside of Bisbee, Ariz.

Henry Martyn Chance, Philadelphia; Jefferson Medical College of Philadelphia, 1881; aged 81; died, February 19, of uremia, hypertrophy of the prostate and arteriosclerosis.

Ralph Ruthwan Shaheen, Flint, Mich.; Loyola University School of Medicine, Chicago, 1936; on the staff of the Hurley Hospital; aged 28; died, February 25, of diphtheria.

Henry Watters © Newton, Mass.; Boston University School of Medicine, 1905; on the staff of the Newton Hospital; aged 55; died, February 19, of coronary thrombosis.

Charles Franklin Hope © Shoals, Ind.; Medical College of Indiana, Indianapolis, 1896; served during the World War; aged 69; died suddenly, March 8, of angina pectoris.

Robert McKown Higley Cotton, Sioux City, Iowa; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1875; aged 87; died, February 1, of senility.

Madison Lafayette Reed, Tilden, Miss. (licensed in Mississippi in 1882); aged 84; died, February 24, at the Gilmore Sanitarium in Amory, of carcinoma of the rectum.

Jay Morehouse Blackman, Quincy, Mich.; Grand Rapids (Mich.) Medical College, 1898; Detroit Homeopathic College, 1900; aged 63; died, March 8, of heart disease.

John Thomas Middleton, Edinburg, Ind.; Medical College of Ohio, Cincinnati, 1890; bank president; aged 75; died, February 28, in Key West, Fla., of heart disease.

William Seward Manuel, Portsmouth, N. H.; University of Vermont College of Medicine, Burlington, 1885; aged 75; died, February 18, at Rye, of cardiac asthma.

Columbus C. Sheets, Ellsinore, Mo.; American Medical College, St. Louis, 1889; aged 75; died, February 23, of bronchopneumonia and cerebral hemorrhage.

Lydia Stockwell, Atchison, Kan.; Ensworth Medical College, St. Joseph, Mo., 1897; aged 89; died, February 26, in the Atchison Hospital, of cerebral hemorrhage.

James C. Hughes, Boston; Middlesex College of Medicine and Surgery, Waltham, Mass., 1923; aged 41; was found dead, February 23, of acute dilatation of the heart.

Joseph Addison Lipscomb, Memphis, Tenn.; Medical College of Virginia, Richmond, 1865; Civil War veteran; aged 94; died, February 23, of bronchopneumonia.

Henry Walter Krohn, Kane, Ill.; Rush Medical College, Chicago, 1891; aged 69; died, February 23, at Our Savior's Hospital, Jacksonville, of pneumonia.

Richard Lafayette Miller, Florala, Ala.; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1895; aged 83; died, February 22, of chronic myocarditis.

Othello L. Deitch, Indianapolis; Medical College of Indiana, Indianapolis, 1890; aged 72; died, February 27, in the Methodist Hospital, of a cerebral hemorrhage.

John W. Hodge, Niagara Falls, N. Y.; New York Homeopathic Medical College, 1881; aged 85; was found dead in bed, February 18, of coronary occlusion.

CONTRACEPTIVE ADVICE, DEVICES AND PREPARATIONS

To the Editor:—The April 3 issue of THE JOURNAL carried an editorial discussing the recent decision of the Circuit Court of Appeals for the Second Circuit in the case of *United States v. One Package* (86 F. [2d] 737 [1936]) and taking issue with the interpretation accorded to that case by the National Committee on Federal Legislation for Birth Control, Inc. Unambiguously entitled "Contraceptive Advice, Devices and Preparations Still Contraband," the editorial derogates the importance of the case which the National Committee has hailed as a significant victory for medical workers in the field of contraception.

The case involved the legality under the tariff act of 1930 (the correct statutory citation is 19 U. S. C. A. No. 1305; in the editorial it was incorrectly given as 18 U. S. C. A. No. 396) of a physician's importing pessaries for use in her practice. The court decided that, despite the existence of a flat prohibition of the importation of "any article whatever" for the prevention of conception, such importation was legal if the importation was for a legitimate purpose, the legitimate purpose in this case being the declared intent of an accredited physician to use the pessaries in the course of her practice to protect health and preserve life. Of the decision, the editorial asserts (1) that "outside its own circuit" it "is not binding but is only of persuasive influence" and (2) that the decision "has and can have nothing to do with the legality or illegality of the practice of contraception within any state except as that practice may involve foreign or interstate commerce or the use of the mails." The inference is that the recently asserted freedom of the medical profession from the crippling bans of obscenity statutes is chimerical and that the decision of the Second Circuit Court is of only passing importance outside the states of New York, Connecticut and Vermont, which are within its jurisdiction. For the rest, the editorial intimates that physicians are still under a disability to avail themselves of contraceptive techniques.

These editorial conclusions rest on several basic misconceptions of fact. At the present time there is every indication that the disabilities of the medical profession in the field of contraception have been dissipated so far as both federal and state laws are concerned.

AS TO FEDERAL LAW

It is true that the decision of the Circuit Court of Appeals for the Second Circuit standing alone would be of only "persuasive" significance. But it does not stand alone. In the first place, two other circuit courts of appeals have clearly taken the same position of liberal construction as that adopted by the court for the second circuit: the Circuit Court of the Sixth Circuit in the case of *Davis v. United States* (62 F. [2d] 473 [1933]) and the Circuit Court of the Seventh Circuit in the case of *Bours v. United States* (229 Fed. 960, 964 [1915]). Together the sixth and seventh circuits comprise Ohio, Kentucky, Tennessee, Michigan, Illinois, Indiana and Wisconsin. Thus, three federal appellate courts, all very highly regarded, are standing together, and it is very unlikely that any other circuit court will disagree with the conclusions they have reached, especially since in the construction of federal statutes conformity of the various circuits is always sedulously strived for and almost always achieved. There has been no hint of dissension.

In the second place, the editorial fails to point out that the solicitor general openly signified his intention not to seek a review by the United States Supreme Court of the decision of the Second Circuit, and no appeal can now be taken. The decision thus stands as the last word on the subject. The central law enforcement authorities have in effect committed

Gaines L. Coates, Pittsburg, Calif.; California Medical College, San Francisco, 1896; aged 64; died, February 3, of chronic myocarditis and bronchopneumonia.

Harry G. Spurrier, Brookeville, Md.; University of Maryland School of Medicine, Baltimore, 1889; aged 70; died, February 12, of coronary thrombosis.

Alfred Thomas Triplett, Fort Worth, Texas; Physio-Medical College of Texas, Dallas, 1903; aged 78; died, February 27, of coronary occlusion.

Allen C. Canfield, Toledo, Ohio; Physio-Medical College of Indiana, Indianapolis, 1882; aged 81; died suddenly, January 29, in his home near Rossford.

Robert Edward Harris, Kingston Springs, Tenn.; Vanderbilt University School of Medicine, Nashville, 1896; aged 72; died, February 13, in Nashville.

William Cornelius Horn, Pennville, Ind.; Miami Medical College, Cincinnati, 1880; aged 83; died, February 27, of diabetes mellitus and prostatitis.

Carl Gustav Kroning, St. Charles, Minn.; University of Minnesota Medical School, Minneapolis, 1933; aged 31; died, February 22, of hypertension.

Charles Winter Woods, Jerome, Ariz.; Eclectic Medical College of the City of New York, 1882; aged 78; died, February 11, of lobar pneumonia.

Edward Augustus Bemis, Batavia, Wis.; Chicago Medical College, 1888; aged 72; died, February 23, of arteriosclerosis and hypostatic pneumonia.

Oscar E. Glover, Bernice, La.; Kentucky School of Medicine, Louisville, 1896; aged 64; died suddenly, March 3, of coronary thrombosis.

Elmer G. Kriebel, Norristown, Pa.; Jefferson Medical College of Philadelphia, 1894; aged 69; died, February 19, of coronary occlusion.

Elmer Joseph MacDonald, Boston; Medico-Chirurgical College of Philadelphia, 1898; aged 64; died, February 26, of bronchopneumonia.

Alvin P. Dewey, Elgin, Ill.; Rush Medical College, Chicago, 1884; aged 77; died, March 30, of chronic myocarditis and hypertension.

George Everson Jr., Brooklyn; Dartmouth Medical School, Hanover, N. H., 1885; aged 79; died, March 6, of coronary thrombosis.

Hudson Ralph Willse, Westfield, N. Y.; University of Buffalo School of Medicine, 1900; aged 61; died, February 27, of myocarditis.

George L. Summers, Huntington, W. Va.; Eclectic Medical Institute, Cincinnati, 1891; aged 68; died, February 2, of coronary disease.

Charles F. Howard, Buffalo; University of Buffalo School of Medicine, 1878; aged 82; died, February 14, of carcinoma of the prostate.

George T. Armstrong, Osceola, Iowa; College of Physicians and Surgeons, Keokuk, 1885; aged 74; died, March 3, of influenza.

Edward John Richstein, Mesa, Ariz.; St. Louis University School of Medicine, 1903; aged 56; died, February 25, of influenza.

Ben P. Sanders, Chilhowie, Va.; Medical College of Virginia, Richmond, 1880; aged 81; died, February 6, of senile dementia.

James B. Gurley, Loganville, Ga.; Atlanta Medical College, 1893; aged 75, died, February 23, of nephritis and arteriosclerosis.

Sergey Nikolaevich Baryborov, San Francisco; University of Moscow, Russia, 1908; aged 56; died, February 8, of coronary sclerosis.

Meyer Jacobstein, New York; Long Island College Hospital, Brooklyn, 1909; aged 65; died, February 17, of heart disease.

Charles L. Muhleman, Parkersburg, W. Va.; Homeopathic Hospital College, Cleveland, 1882; aged 82; died, February 13.

Howard Webster Knight, Saco, Maine; Dartmouth Medical School, Hanover, N. H., 1899; aged 78; died in February.

G. W. Yates, Hector, Ark. (licensed in Arkansas in 1905); aged 67; died, February 18, of cerebral hemorrhage.

James B. Funk, Fort Wayne, Ind.; Fort Wayne College of Medicine, 1884; aged 78; died, in March, of uremia.

Samuel B. Smith, Cleveland; Ohio Medical University, Columbus, 1900; aged 66; died, February 3.

themselves to accept it as final and consequently to abide by its terms. On the basis of the decision, new instructions have issued to customs officials from Washington, calling it to mind and prescribing a new procedure whereby physicians or their duly constituted agents may by the presentation of an affidavit of legitimate purpose secure the passage through the customs of contraceptive materials.

In the light of these facts and adjudications, the fear that physicians will run afoul of federal law if they use the mails or the channels of interstate or foreign commerce to ship contraceptive materials or information in the course of their regular medical practice appears to be totally unwarranted.

AS TO STATE LAW

To state that the decision "has and can have nothing to do with the legality or illegality of the practice of contraception within any state except as that practice may involve foreign and interstate commerce or the use of the mails" is to slur over a vital exception and to disregard the past effect of federal decisions of this nature on state courts. In forty of the forty-eight states, physicians are and have been free to act in the field of contraception. Of these forty, some do not have laws on the subject of contraception at all, others have laws regulating only the advertising of contraception; still others forbid the giving of advice and the selling of materials but except physicians from their prohibition. In these forty states the major legal obstacle to the proper functioning of doctors in the field of contraception was the federal law. In rural and outlying areas, lack of access to the mails and the ordinary channels of interstate transportation, often the only source of supply, may be crippling to the point of annihilation. A ruling which tends to an easier transmission of contraceptives to physicians has something vital to do with the functioning of public and private health agencies within the confines of a single state. Moreover, as to the eight states which flatly prohibit activity in the contraceptive field, the ruling is not by any means without significance. Where federal and state statutes are similar in purport, state authorities have consistently patterned their interpretations on the holdings of the federal judiciary. No book cleared through the federal customs as free from taint of obscenity has ever been made the basis for a conviction on the grounds of obscenity under a similar state statute in a state court; rarely if ever has such a book been subsequently made the basis of a prosecution although previously suspect or attacked by state law enforcement agencies. For example, although the book "Ulysses" by James Joyce had been previously made the subject of prosecution under New York law, once it was cleared through the customs by the holding of a federal court it was never again challenged. True that the eight states which have absolute and unconditional bans on contraception may legally refuse to be influenced by a federal decision; one of them, Massachusetts, however, had even before the recent decision of the second circuit evolved the same kind of liberal interpretation of an apparently unlimited prohibition. (*Commonwealth v. Dr. Clayman*, District Court in Chelsea, Mass., August 1935). There is no reason to suppose that the other seven will not adhere to the normal course of following the lead of the federal government in this regard, especially since every dictate of public policy and sound reasoning is on the side of conformity.

So much for what the editorial says. A word should be devoted, however, to those things which the editorial does not say. It completely fails to point out the tremendous scope of the decision of the court in *United States v. One Package*. The decision is particularly significant in two respects 1. It lends support to a very wide definition of "legitimate purpose," for the doctors who testified in the course of the trial included, among the factors which they thought would warrant them in prescribing a contraceptive, economic as well as physiologic ills. This testimony is contained in the printed record and is an

indication of the breadth of the decision which was based on it. 2. The court assumed that the same interpretation which was here accorded to the importation statute would be accorded to the statutes dealing with the mails and with use of the facilities of interstate commerce. It is generally conceded that these three statutes ought to be construed identically, and it was so assumed by the writer of the editorial; but the decision in this respect is especially clear and comprehensive. Finally, to fail to allude to the customs ruling described above is to neglect to state an acknowledged and highly important result of the decision. Cases such as the very one commented on are from now on very unlikely even to arise, since the affidavit of a doctor or his agent suffices to insure the release of any articles which might be even temporarily detained. If the point of view of the writer of the editorial were adopted, physicians would be unable to take advantage of the freedom to which agencies entrusted with enforcement of the laws they fear to violate say they are fully entitled.

When the decision of the Second Circuit Court of Appeals is thus viewed in the setting of which it is an integral part, and the full extent of the holding called to mind, the claims made for it by the National Committee on Federal Legislation for Birth Control appear to be fully warranted. The warning to the medical profession that "contraceptive advice, devices and preparations [are] still contraband" is seen not to rest on either a sound or a thorough analysis of the present legal situation, and it can serve only the purpose of seriously impeding further progress in what is concededly an important branch of preventive medicine. In view of the seriousness of the errors made and the vital import of the problems discussed, correction should not be long in forthcoming.

Legal Advisory Committee of the National
Committee on Federal Legislation for
Birth Control, Inc.

[This letter was referred to the Bureau of Legal Medicine and Legislation. Dr. W. C. Woodward, the director, replies:]

To the Editor:—The decision of the United States Circuit Court of Appeals for the Second Circuit, December 1936, in *United States v. One Package*, 86 F. (2d) 737, added nothing to decisions previously rendered by various courts further than the rule that contraceptive devices may lawfully be imported into the United States for the preservation of health. One of the three judges accepted the judgment of his associates with respect to the matter but expressed grave doubts as to its correctness. Under such circumstances, the weight that other courts will give this decision is purely speculative. Certainly it is not "a bill of rights for the medical profession," nor does it authorize physicians to give contraceptive advice "in public as well as private practice," as the National Committee on Federal Legislation for Birth Control, Inc., proclaimed. As the committee's propaganda seemed likely to bring physicians unwittingly into conflict with federal and state laws, THE JOURNAL undertook to inform them correctly concerning the situation. Nothing in the letter from the committee's legal advisers seems to sustain the broad claims made by the committee in the publicity material that it issued to the medical profession, or to do away with the necessity for a physician who desires to recommend contraception or to supply materials and devices for that purpose informing himself concerning the laws relating to contraception in the community in which he is practicing and governing himself accordingly.

W. C. WOODWARD, M.D., Chicago.
Director, Bureau of Legal Medicine
and Legislation.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

ALBUMINURIA IN BOY

To the Editor:—A few days ago I examined a youth, aged 18 years, for an insurance company. I could find no abnormality in the physical condition. The teeth and the tonsils were in good condition. The sinuses were clear. The chest was clear. The temperature was 98.6 F. There were no abnormal heart sounds. The blood pressure was 125 systolic, 89 diastolic. The medical history was absolutely negative. The only childhood diseases that he had were measles and whooping cough. The urine examination was as follows: specific gravity, 10.20; acid in reaction; no sugar. There was a definite white ring when examined for albumin with the nitric acid test. The insurance company also found albumin. His insurance company advised him to place himself under a physician's care for six months. At the end of that time he would be considered again for a policy. I have searched for the cause of the albuminuria and I am not able to find it. The boy has never been sick. He works hard on the farm and he would never have known that this albuminuria existed had it not been for his desire to take out insurance. I might say that the father took a policy on all the children, two boys and two girls. The 18 year old boy is the only one who showed any abnormal condition of the urine. I should like to know what kind of a program one should indicate for this boy to clear up the condition.

A. H. REISWIG, M.D., Fairmount, N. D.

ANSWER.—Obviously the first problem presented by this case is one of accurate diagnosis. The query states that the cause of the albuminuria has been searched for. But how was this done? There are two major situations that must be differentiated. Either the proteinuria is an evidence of otherwise silent renal injury (early nephritis, unless acute, is typically asymptomatic) or the albuminuria is wholly benign. There are many including the conservative life insurance medical directors, who deny the existence of any wholly benign proteinuria. On the other hand, much evidence has accumulated to indicate that so-called orthostatic albuminuria may exist for years without being the precursor of nephritis.

Orthostatic albuminuria (often also called lordotic, postural or adolescent albuminuria) is characterized by the appearance of considerable quantities of protein in the urine that is secreted while the patient is erect, with temporary cessation of the albuminuria in the urine secreted while the patient is reclining. Effort, such as walking vigorously or running, increases the albuminuria. It is found most commonly among underweight adolescents and youths up to the age of 25, and is more frequent in girls than in boys. The lordotic posture is usually but not invariably detectable. In the majority of cases the syndrome disappears spontaneously with maturity and with the gain in weight which comes at that time. There is no detectable impairment of renal function. It has been presumed that this postural albuminuria is due to torsion or pressure on the renal pedicle in the erect position with interference with the renal circulation. Similar postural effects are observed in patients with freely movable kidneys. In connection with the present case, nothing is mentioned in the query regarding the physique of the patient. The most significant evidence of orthostatic albuminuria can be obtained by comparing urine specimens voided immediately after arising in the morning (urine secreted while recumbent) with others voided after activity. In orthostatic albuminuria the early morning specimens will be completely free from albumin. It must be emphasized, however, that in Bright's disease there is a postural element which increases the proteinuria when the patient is active. Therefore careful microscopic inspection of the urinary sediment is necessary to rule out the presence of a few erythroplasts and/or casts as evidence of true nephritis.

More probable in this case is the conclusion that the albuminuria is evidence of a low grade nephritis. The query states that no abnormality in the patient's physical condition could be detected. This statement is not wholly accurate: A diastolic blood pressure of 89 is distinctly above normal for a boy of 18 years. The mean normal for this age is 76 and the maximum normal 84. The one reading is, of course, of relatively little significance, for the boy may readily have been excited. Repeated observations are absolutely necessary, and if the diastolic tension is found persistently in the neighborhood of 90 mm. or higher it may be taken as additional evidence of renal injury and impairment. Renal function studies are indicated before attempting therapy. The renal concentration test (*Queries and Minor Notes*, *THE JOURNAL*, Feb. 8, 1936, p. 484) and the

phenolsulfonphthalein test are simple office procedures and should be carried out. The renal concentration test should be considered as the most sensitive index to early impairment. It is a stress procedure and thus reveals otherwise hidden depreciation of the renal reserve.

If the boy has an orthostatic albuminuria, the most important therapeutic considerations are (1) a diet adequate in protein not only to replace the protein lost in the urine but also to yield sufficient for growth and development; (2) adequate calories to correct any underweight that may exist; (3) correction of anemia, should it be present. The treatment of an early, mild nephritis is along parallel lines with the additional consideration that search of sources of injury must be thorough and complete; foci of infection, unwise dietary habits (especially the abuse of condiments), chilling and any source of intoxication require review. It is observed that the urine of such patients is frequently alkaline, whereas the normal human urine is acid. An acid-ash diet (compatible with the liberal protein intake) is preferable to an alkaline one.

TRAUMA ACTIVATING SYPHILIS

To the Editor:—A member of the company received a blow over the sternum and complained of pain in the sternal region. A temperature of 99 to 100 F. was present. This pain and temperature continued for about two weeks, the temperature usually being normal or slightly above in the morning and rising in the afternoon. Physical, x-ray and other studies failed to reveal the cause of the complaints. Fracture and tuberculosis could be excluded; finally a blood test (Kahn) was reported positive. Another man received a blow in the middle of his forehead, which caused a small laceration. This was repaired and healed well. Headaches, however, have persisted since that time. Fracture and sinus infection can be excluded. As the cause of the headache was not found a blood test was made and found positive. I should like to know whether a "latent" syphilis could be activated by such seemingly insignificant trauma or by any trauma. Both men were well prior to the injuries and there was no history of syphilitic infection. If published please omit name.

M.D., Michigan.

ANSWER.—There can be no question of the importance of trauma as an unfavorable influence in syphilis from the beginning to the end of the infection. It is an axiom of the older clinical syphilology that one may always find latent or concealed syphilis becoming outspoken at a locus minoris resistentiae. The experimental evidence developed by Chesney and by Greenbaum and Madden tends to indicate that the reaction induced does not necessarily involve the actual presence of *Spirochaeta pallida* and that the local tissue response is not necessarily that of gummatous breakdown, as clinical experience alone would seem to suggest. Thus it is possible for a blow on the head to give rise to the onset of symptoms of dementia paralytica and *pari passu* of other seemingly remote symptomatic revivals of what had up to the time of injury been apparently a latent infection. Thus the fever in one patient and the headaches of the other are quite within the range of symptomatic lighting up of a latent syphilitic infection producible by seemingly minor trauma. Klauder and Solomon have gone extensively into the medicolegal status of the relation of trauma to dementia paralytica and no doubt the principles applicable there could be given wider significance were compensation commissions as well as industrial medical staffs more disposed to submit the problems involved to inquiry and adjudication. Gougerot and Clara have pointed out that every type of injury, mild or severe, sudden or prolonged, single or repeated, may serve to excite reaction on the part of a syphilitic infection.

It does not, however, follow that every trauma invariably gives rise to syphilitic reaction in a victim of the disease. It is therefore necessary in all cases to exclude rigorously by the most careful examinations all collateral possibilities. As head trauma is particularly known for its ability to revive or activate syphilis of the nervous system, a spinal fluid examination might well be considered in order if persistent headaches follow trauma in a case of latent syphilis. The same rule can properly be applied to the latency of a patient with fever, for in no case should the mere recognition of a positive blood serologic test for syphilis stop further investigation of the extent and character of the involvement for which the disease may be responsible. Only after an adequate investigation, which should certainly include a spinal fluid examination in cases like this, is it justifiable to institute a therapeutic test. It is discreet, to say the least, to begin such a therapeutic test with a heavy metal such as bismuth rather than with one of the arsphenamines, even though the spinal fluid is negative—for localized gummatous and vascular syphilitic lesions of the nervous system are not infrequently accompanied by negative spinal fluid examinations and yet may be flared up to disastrous or near-disastrous complications by the therapeutic shock administered by injudiciously used arsphenamine.

FATALITY FOLLOWING INJECTION OF
VARICOSE VEIN

To the Editor:—A married woman, aged 41, white, a quadripara, had smallpox at the age of 22, measles at 14 and influenza in 1918. The functional inquiry brought negative replies except for dizziness on sudden change of posture. Examination in 1924 was essentially negative except for the notation of a "slightly rapid pulse." The blood pressure was 130 systolic, 86 diastolic. Later parts of the record noted "heart o. k." several times. My own record begins in 1931 and was for pregnancy. There is nothing of any further significance except for the same complaint of dizziness on sudden change of posture and increasing difficulty with varicose veins. Early in 1934 I began a series of vein injections using quinine and urethane at the start and later changing to 5 per cent sodium morrhuate. The patient had a total of twelve injections, of which probably one half were of sodium morrhuate. In 1935 I again took care of her through a pregnancy with nothing more significant appearing than some edema of the ankles and trouble with the remaining varicosities. She was delivered normally in March 1935. The blood pressure during that pregnancy ranged from 138/80 to 145/90. A few days ago she came in and had several small varicose ulcers on one leg. It was evident that the internal saphenous vein was open from the ankle up. This vein had been well occluded, I thought, at the end of the treatments in 1934, but at any rate it was open the other day. I prepared to give her an injection of sodium morrhuate. I used a fresh 5 cc. (5 per cent solution) rubber capped vial (Breon Company, Kansas City, Mo.). The vein was easily entered. A small amount injected caused the complaint of severe burning in the vein, so I stopped and pulled back the plunger. It was still in the vein, so I injected a little more. The pain was again severe, so I stopped. With the blood in the syringe it was hard to say the exact amount injected, but it was something less than half of the 5 cc. She reacted rather queerly, seeming somewhat faint and complaining of very severe pain all the way up the vein and even into her back. I had her lie down and kept her at the office for two hours. It was soon noticeable that the entire foot was very blue and cold, the discoloration extending toward the knee and, of course, getting less farther up. The pulse was rather weak and rapid at times, so I gave her 0.5 cc. of 1:1,000 epinephrine. After two hours she seemed much better and ready to go home. I helped her out to my car, intending to take her home, but just as we got to the car she went "out." I managed to get her leveled out between the seats and gave her the other 0.5 cc. of epinephrine. She was out so deeply that the bladder was emptied. Not wanting to risk further attacks, I got the ambulance and as soon as she had brightened up a bit I moved her on the cot and took her to my home and put her to bed. She was improving rapidly by this time and had not been long in bed until she seemed quite all right. The pulse, the blood pressure and the color were all good and incidentally the foot was now warm and of natural color. About four hours later her relatives became rather urgent about taking her home as she felt all right. I was reluctant to let her go but could not see any reason for insisting that she stay, so after trying her in a chair a while I helped her walk a few feet to the car. We were no more than in the car when she went out again. I hurried her back to bed (she returned to consciousness rather quickly but remained in shock) and I used 0.5 cc. of epinephrine and digalen (1 ampule intravenously) and morphine and heat to try to bring her out of her shock, but she just kept going deeper and died about two hours later. The digalen was just a forlorn hope. I realized that it was not particularly indicated but I was desperate and nothing else seemed to be helping. I also gave some 50 per cent dextrose intravenously. The only symptoms I can describe during that period are very rapid, weak pulse, often barely perceptible at the wrist, pallor, and toward the last cyanosis, sweating and retching. I wrote "shock probably anaphylactic" on the death certificate. It was certainly shock but could it have been anaphylactic? Is there such a thing as sensitization to sodium morrhuate? Or is it possible that this solution has become toxic in some way? I have two more of the ampules and I should like to know where I might send them for analysis. I do not know whether this story will give you enough to go on to allow you to voice an opinion, but I hope so, and I also hope that some benefit to others may come from the case. It broke me up badly to have it happen but I acted as it seemed best at the time. M.D., Nebraska.

ANSWER.—In view of the fact that the general history of the patient up to the doctor's record in 1930 was negative, there was no contraindication in the treatment of the varicosities. The dizziness mentioned was probably due to delayed orthostatic blood pressure response, caused in the act of stooping, possibly an irritable carotid sinus. Quinine and urethane have the most frequent systemic reactions of any of the sclerosing solutions. Patients have gone into shock after the injection of 2 cc. of quinine and urethane, and the blood pressure has dropped. The lowest noted was systolic 58/0? However, there was a return to normal in the course of an hour or so.

The recent repeated treatment with sodium morrhuate certainly was not contraindicated. Undoubtedly the small amount injected may have induced the initial shock, but the extreme repeated collapse mentioned is not an ordinary experience. Sodium morrhuate may have produced an allergic reaction as any drug will do in certain individuals.

We cannot draw any definite conclusions from these reported cases as to the advisability of discontinuing sodium morrhuate or any other sclerosing reagent, as there is evidence that any type of drug may produce anaphylactic reactions, and these reactions are extremely rare compared with the large number of injection treatments given.

There is a remote possibility that this patient had a congenital septal cardiac defect and that following the vein injection a thrombus formed and became dislodged, immediately passing from the right to the left side of the heart and occluding a coronary artery, resulting in a painless occlusion.

There is also a possibility of pulmonary embolism with atypical symptoms, particularly in the second attack. Also there is a possibility of some chemical change in the solution injected. If solution from the same bottle is still available, one might try its effect on an animal.

SYPHILIS WITH SENSITIVITY TO METALS

To the Editor:—A woman, aged 27, had latent untreated syphilis. She gave a history of mucous patches on the genitalia six years ago and two miscarriages shortly thereafter. I began antisyphilitic treatment with weekly injections of nearsphenamine, the first dose 0.3 Gm., the second dose 0.45 Gm., and the remaining doses 0.6 Gm. Following each injection the patient vomited her meals for a period of about twenty-four hours. After the fourth injection of nearsphenamine, a typical picture of agranulocytosis developed: high fever, areas of necrosis in the gums involving also the jaw bones, and a blood picture of 1,200 white blood cells and 4 per cent polymorphonuclears. Response to pentnucleotide and liver extract was prompt and the patient recovered in a week. She was then put on saturated solution of potassium iodide 45 minims (2.8 cc.) daily and weekly intramuscular injections of bismuth salicylate in oil 2 grains (0.13 Gm.). Within a month she lost appetite, she had a brassy taste in her mouth, and a blue line appeared on the gums. The patient is apparently hypersensitive to arsphenamine and has poor tolerance for bismuth. Could you suggest a course of treatment that would be safe and at the same time effective against the syphilis? Please omit name.

M.D., Michigan.

ANSWER.—The intolerance to the metals which this young woman has displayed is sufficient reason to discontinue all antisyphilitic treatment for the time being. It is the usual experience that a patient who develops an agranulocytosis as a complication of treatment with nearsphenamine is also intolerant to the other metals used in the treatment of syphilis. The tendency to react to these drugs may disappear within six months or a year, at the end of which time small doses of bismuth or mercury, one eighth or one sixth of the average dose, may be tried with caution, but one drug being administered during the course. The leukocyte count in such a patient is often an indicator of impending reactions, and the appearance of a leukopenia should be the warning sign to stop treatment again. If reactions are produced by these drugs in small doses, the avoidance of treatment is warranted.

The question of this patient's infectiousness and the likelihood of the syphilis progressing are for the time being of secondary importance. As she has had the infection for six years, there is small possibility of her transmitting the disease, and because she is in the latent phase of syphilis, the likelihood of her developing clinical evidence of syphilis within a year is remote. The patient should, however, be cautioned forcibly against becoming pregnant.

NEUROCIRCULATORY ASTHENIA AND CARDIAC NEUROSIS

To the Editor:—An executive, aged 61, who has always enjoyed excellent health despite the fact that he always worked at high pressure, recently received a severe shock in the accidental death of his favorite son in an automobile accident. Since then he has had pain in the precordial region and at times, even in the dead of night, is apprehensive. I am unable to find any evidence of heart involvement and careful examination shows no evidence of focal infection except for two dead teeth. A rough Schneider test reveals:

	Pulse	Blood Pressure	
		Systolic	Diastolic
Prone	70	120	72
Sitting	72	120	72
Standing	74	120	74
Immediately after exercise.....	126	170	76
Three minutes after exercise.....	74	124	70

When he arrives at our office his systolic pressure varies from 114 to 150 and I am in a quandary as to what type of treatment to institute. A trip to the sea shore only resulted in an increase in symptoms and he returned home to "take care of the tag ends" of his business. Any suggestions you may give me to stabilize his vascular system will be deeply appreciated. Please omit name.

M.D., Wisconsin.

ANSWER.—The diagnosis in this case seems to be that of neurocirculatory asthenia and cardiac neurosis dependent primarily on fatigue and the nervous strain from the severe shock caused by the accidental death of the favorite son. There is no evidence of heart disease, although at the age of 61 one must be very careful to rule out such evidence, the discovery of which would be of some importance in the production of symptoms and to help in regulating the patient's life in the future. For the sake of completeness, an electrocardiogram should be taken.

In the absence of evidence of heart disease the prognosis as to longevity is probably good, although one would like to know the longevity of the parents and grandparents.

Certainly in the way of treatment sympathetic reassurance in repeated doses, a long holiday, and a reform of his way of living are the measures to be recommended. The holiday should be in some place where much pleasure and leisurely distraction are possible.

TOXIC OR RHEUMATIC HEADACHE

To the Editor:—About ten months ago while employed at a soda fountain, the patient noticed a sensation in his head, close to the surface, as though something were crawling about. This sensation was confined to a definite area about 3 cm. in diameter and about 3 cm. to the right of the midline and a line corresponding to the external auditory meatus. This sensation continued for about a month, when it changed to a dull aching feeling. About two weeks after the original onset and before it had changed to a dull ache, he would notice a feeling of tingling and numbness in his right upper extremity. This feeling in his right arm would come on only while he was reclining, as before going to sleep or on awakening from sleep, and would not be experienced while he was up and around working. These sensations in his arm lasted for only about two weeks and have never recurred. The dull aching feeling in his head however has persisted, although it has been relieved from time to time by sedatives. His past history included measles and chickenpox in his childhood, appendectomy in 1928 and pneumonia in 1930. As he remembers it, the attack of pneumonia did not include meningeal or encephalitic symptoms. His family history is negative. Both of his parents and his one brother are living and well. The patient is a white man, aged 28, weighs 160 pounds (73 Kg.), is about 5 feet 11 inches (180 cm.) in height and has a blood pressure of 112 systolic, 68 diastolic, a pulse rate of 84 and normal temperature. There are no palpable masses in the cranium and no tenderness on percussion over the area involved. The eyes reacted equally to light and in accommodation. The eyegrounds appeared normal, though very satisfactory views were not obtained as the eyes were not dilated. The ear drum on the right side was dull, with only a suggestion of the light reflex remaining. The tonsils appeared necrotic, as though chronically inflamed. He had one carious tooth, but this was extracted a week or so before. There were no palpable cervical glands nor was there any palpable enlargement of the thyroid gland. The heart, lungs and abdomen, as well as the extremities, were normal. The Romberg sign was negative and the deep reflexes all appeared normal. There was no disturbance of the motor, stereogenic or kinesthetic senses. Red blood cells numbered 4,250,000, hemoglobin was 90 per cent, and the Wassermann reaction has been repeatedly negative. I should like your suggestions as to diagnosis and treatment. YOUNG SAM JENKINS, M.D., Taft, Texas.

ANSWER.—From the dearth of evidence listed it would seem unlikely that the patient has an organic disease of the central nervous system. There may be a definite relationship between the dull aching pain over the right side of the head (parietal scalp) and the infected tonsils. This condition is known as an infectious or rheumatic headache. In some of these cases one is able to palpate small tender nodules over the involved area or in the tissues along the back part of the neck. The treatment is removal of all foci of infection and the giving of some form of acetylsalicylic acid, usually from 1 to 1.3 Gm. a day for a period of five or six weeks. Copious amounts of liquids should be taken daily. Occasionally multiple sclerosis starts off with numbness and tingling in one or two extremities but in this condition the paresthesias are constant until improvement occurs.

SKIN TEST FOR PREGNANCY

To the Editor:—Please furnish me with information on the reliability of the skin test for the diagnosis of pregnancy, as described by Gilfillen and Gregg, using intradermal injection of antuitrin-S. What is the approximate percentage of error in this test and in the Friedman modification of the Aschheim-Zondek test? Please omit name.

M.D., Virginia.

ANSWER.—The work of Gilfillen and Gregg has not been verified by other observers. In a series of more than 100 cases, the reports of which are now being prepared for publication, the value of the test as a reliable indication of the presence or absence of pregnancy is doubtful. A communication from the men doing this work indicates an approximate error in known pregnancies of 10 per cent, in nonpregnant women of 40 per cent (positive tests having been obtained on the urine of menstruating women), and a group of tests on male urine showed a 50 per cent error. From such figures it is difficult to feel that such a test can be used with any amount of satisfaction.

The Friedman modification of the Aschheim-Zondek test is a reliable procedure, showing correct results in about 98 per cent of checked cases. At present it is felt that for the most reliable and satisfactory tests for pregnancy we must rely on the Aschheim-Zondek (99 per cent correct) or Friedman tests in spite of their more complicated technical workings.

WORRY OVER SIZE OF SEX ORGANS

To the Editor:—A white man, aged 37, a cab driver, strong and healthy, is developing a neurosis through intensive brooding over the fact that his penis and testes are somewhat smaller in size than the average. He fears this denotes "lack of manhood." He appears normal on general physical examination and all routine laboratory procedures. Detailed genitourinary examination reveals no abnormalities except that the penis, scrotum and testes are all somewhat undersized. There is no history of venereal infection, parotitis or any disease or trauma specifically affecting the genitals. He is sexually normal in every way, the semen containing an abundance of live active spermatozoa. Do you think intensive treatment with gonadotropic extract of pregnancy urine would stimulate the genital growth in this case to any appreciable extent?

M.D., District of Columbia.

ANSWER.—It is an exceedingly common experience for a sexologist to be consulted by men who are sexually normal but who worry because their sexual organs are smaller than those of other people. They are especially ashamed when using a public bath and fear that others will notice their small genitals. The patient will be comforted by being told that the penis has two functions, that of urination and that of sexual connection. If it can perform both these functions, it is to be considered normal. In other words, the patient must not worry how small the organ is in the ordinary condition as long as during connection it gets large enough to penetrate the female genitals to his and his partner's satisfaction.

As to the use of gonadotropic substance, it is doubtful whether it would have any effect on the size of the genitals in a man of 37.

TREATMENT OF PHLEBITIS

To the Editor:—One year ago last December a patient came to my office complaining of pain in the right leg following a hunting trip of a week's duration. Examination revealed an early phlebitis of the right leg. The patient was confined to bed with elevation of his extremities and application of dry heat to the extremity. That night the patient had an embolus to the left lung causing frothy blood-tinged expectoration, pain in his left chest, dyspnea, cough and increased pulse rate. Following this a left pleural effusion caused so much discomfort and dyspnea that aspiration was necessitated, resulting in withdrawal of at least 1,000 cc. of serosanguineous fluid at each aspiration. The phlebitis of the leg advanced proximally through the saphenous vein and thence to the iliacs, crossing over to the left thigh and leg and involving both superficial and deep veins. Later the condition advanced to the deep pelvic veins and anterior abdominal veins. This resulted in marked tenderness in the patient's abdomen and back. Absolute rest was maintained for at least four months before the condition abated at all. Later the patient was fitted with elastic stockings and was gradually removed from bed. After a while he was able to get around in a wheel chair. Later he could go about on crutches. He did not have fever, his general nutrition was good and he had no symptoms of further involvement. He then decided to take a short trip to a nearby town, where he had another attack of phlebitis of the anterior abdominal wall. He was immediately confined to bed in a hospital by another physician and kept there for more than a month until this attack abated. He was allowed to return home and had been here for about two weeks when he had another acute attack of phlebitis in the left thigh and leg. He is now in bed again under an electric heat cradle with slight elevation of the legs. He has been receiving additional supportive treatment to maintain his nutrition and prevent anemia. He is quite discouraged, as any one would be after such a long siege of sickness and treatment. He wonders whether he will ever be well again. I am asking for any other therapy that might be given to avoid any further attacks or flare ups of this condition. I have never resorted to any intravenous medication of any sort as all my teachings and readings from authoritative sources have discouraged me in this.

M.D., Wyoming.

ANSWER.—This patient must undergo a thorough examination for possible sources of infection. The tonsils should be inspected and, if necessary, massaged to reveal infection. If they have been removed, remaining stubs should be searched for, as they are often apt to produce absorption. Complete dental x-ray films should be inspected for root abscesses, dead teeth and incomplete fillings. In a case like this, even doubtful teeth should be sacrificed. The prostate must be massaged and a prostatic culture obtained. The thrombophlebitis can also originate in abdominal infections, such as appendicitis or cholecystitis may harbor. He could also have had an ambulatory type of typhoid or paratyphoid infection, which is sometimes followed by phlebitis. Even after all suspicious foci of infection have been removed, attacks may recur following unusual physical strain or injury. The heart must be carefully examined for the possibility of a latent endocarditis, which may follow repeated attacks of deep thrombophlebitis. The course and subsidence of the process may be followed by sedimentation rates. Therapy should consist of thorough eradication of foci and immobilization until the pulse, leukocyte count and temperature have been normal for at least ten days. Small doses (120 roentgens with heavy filter) of x-rays over the areas of phlebitis often hasten the termination of acute attacks.

DIAGNOSIS OF SYPHILIS FROM SEROLOGIC
OBSERVATIONS

To the Editor:—A white youth, aged 20, seen Aug. 11, 1936, because of gonococcal infection of the urethra, had a routine blood examination which showed a 3 plus Kahn reaction. He was hospitalized in another city and was under treatment by another doctor in July 1936 because of extensive trichophytosis of the feet. Physical examination there showed a slight watery urethral discharge, negative for gonococci, present only in the morning, and a few small swollen glands in each groin. Blood tests taken there were Kahn 1 plus and Kahn negative. Physical examination August 11 showed a gonococcal infection of the urethra, a few small palpable glands in each groin, and a mild trichophyton infection of the toes of both feet. The physical examination was otherwise normal. A physical examination August 17 gave the same results. There were no penile sores or scars. Nothing on the skin or mucous membranes was suggestive of primary or secondary lesions. The eyegrounds appeared normal. The heart and central nervous system were normal. Two subsequent examinations have been normal. The patient admits frequent sexual exposures but denies ever having had any sores on the penis, lips or body. He does not recall having had any body rash except measles at 8 years of age. Both his father and his mother died about nine years ago, and he is not very clear about their history. What history is obtainable, however, could fit with that of syphilis. The father died at 44 of "heart failure." He was sick for two and one-half years. He had a stroke at 41 affecting the left side of the body. His mother died at 44, having been a mental case for about one and one-half years. One brother is living and well. No brothers or sisters have died in infancy. So far as the patient knows, the mother had no miscarriages or stillbirths. The patient received sixteen weekly intramuscular injections of a bismuth compound from Sept. 28, 1936, to Jan. 1, 1937. No other treatment of an antisyphilitic nature has been given. The blood became negative after the third injection of bismuth and has remained so except for one doubtful reading. Incidentally, the trichophytosis cleared up at about the same time the blood became negative. Blood examinations were made as follows:

Laboratory 1.....	7-28-36	Kahn 1 plus
Laboratory 1.....	8- 6-36	Kahn negative
Laboratory 2.....	8-17-36	Kahn 3 plus
Laboratory 2.....	8-24-36	Kahn 3 plus
Laboratory 2.....	8-31-36	Kahn 1 plus
Laboratory 2.....	9- 8-36	Kahn 3 plus
Laboratory 2.....	9-14-36	Kahn 3 plus
Laboratory 3.....	9-14-36	Kahn 3 plus Wassermann neg.
Laboratory 4.....	9-14-36	Kahn 3 plus Wassermann neg.
Laboratory 2.....	9-28-36	Kahn 2 plus
Laboratory 2.....	10-26-36	Kahn negative
Laboratory 2.....	11- 2-36	Kahn negative
Laboratory 2.....	11-30-36	Kahn doubtful
Laboratory 2.....	12- 7-36	Kahn negative
Laboratory 2.....	1- 4-37	Kahn negative

Spinal fluid examination: Laboratory 3, 9-14-36, cells 17, Kahn negative, Wassermann negative, globulin slightly positive, colloidal gold 0000000000. Is a diagnosis of syphilis justified from the results of the blood tests and reversal to negative with three injections of the bismuth compound? If so, what plan of treatment would you recommend?

M.D., Connecticut.

ANSWER.—The serologic reactions do not form sufficient ground on which to warrant an unqualified diagnosis of syphilis. The absence of a history and clinical manifestations of syphilis adds weight to the suggestion that the serologic reports are nonspecific or false positives. The majority of serologists do not believe that nonspecific positive tests occur; they prefer to believe that the serologic test has such a high degree of specificity that nonspecific or false positives do not occur. Clinicians, however, repeatedly see positive serologic reports of nonspecific nature.

For the case in question it is suggested that a specimen of blood be drawn, divided equally into two parts and each half sent to a different laboratory. If both laboratories report positive tests, treatment with neoarsphenamine and a bismuth compound should be continued. If the tests are reported negative, the patient should be placed on observation and the tests repeated in six months. The need for treatment in the future will be dependent on the subsequent serologic reactions.

USE OF CALCIUM AND COD LIVER OIL IN PREG-
NANCY TO PREVENT DENTAL CARIES

To the Editor:—Is there conclusive evidence that the use of calcium and cod liver oil during pregnancy prevents dental caries in the mother? In a woman prone to dental caries but otherwise completely healthy from every standpoint and examination, does the prolonged use of calcium and vitamin D products prevent or retard caries? Please omit name.

M.D., New York.

ANSWER.—It is difficult to produce "conclusive" evidence that the use of calcium and cod liver oil during pregnancy prevents dental caries in the mother. In spite of this, several authors have expressed definite opinions on this subject. Vignes (*Progrès méd.* 43:477 [March 24] 1928) from a study of the literature and his own experience maintains that an insufficiency of calcium leads to dental caries. Richardson (*Illinois M. J.* 59:453 [June] 1931, 65:367 [April] 1934) states that dental caries and brittleness of the teeth during pregnancy may be

improved in ten days by the use of viosterol and absolutely and completely arrested in two weeks when adequate dosage is employed. Dentists requested to check up on these observations reported an increased hardness in the carious surfaces after viosterol. This hardness, according to Richardson, represented a recalcification of the decalcified dentin.

There is abundant evidence from the work of Maxwell and Miles in China and of Green-Armytage in India and others that osteomalacia is a deficiency disease and that the main deficiency is a lack of vitamin D. This disease may be stopped and cured during pregnancy provided a proper supply of vitamin D and calcium is given.

Danforth (*Illinois M. J.* 69:219 [March] 1936) states that vitamin D influences growth both in laboratory animals and in man. Lack of this vitamin results in deficient calcification, causing the production of soft, fragile, bony structure. Vitamin D exerts a definite effect on calcium and phosphorus absorption and for this reason an adequate supply should be provided for the pregnant woman. In warm weather, simple exposure to the sun provides an efficient and inexpensive method of supplying the needed vitamin D, provided sufficient precursor is present in her own tissues, but in winter, particularly in the colder parts of the country, the administration of viosterol is of great value, especially if combined with calcium and phosphorus.

In view of the foregoing opinions and especially because the possibility of overdosage of these substances is remote, this patient who is prone to dental caries should be given an abundance of calcium and vitamin D.

HYDROCELE

To the Editor:—An 8 year old boy was operated on for hydrocele, which after about six months has returned. Could satisfactory results be expected from injection therapy? As the patient has a slight allergic history, what preparation could best be used? Should a skin test be done before injection?

M.D., Connecticut.

ANSWER.—It is unusual to have a hydrocele recur after a radical operation. The question arises whether the patient informed the doctor correctly; it is possible that the hydrocele was tapped and not operated on. If the patient has a recurrence he should be operated on and not have injection therapy.

THE APPENDIX AND COLONIC PERISTALSIS

To the Editor:—In THE JOURNAL, April 3, in Queries and Minor Notes, page 1201, I observe that to the question whether "the appendix is the initiator of peristalsis of the colon," propounded by Dr. J. Marsh Frere, your reply is "There is at present no evidence that the appendix in any way governs the movements of the colon."

I beg leave to submit the following quotations from my book on Appendicitis (New York, D. Appleton & Co., 1927, p. 28) as justification for the query and possibly throwing some light on the subject:

"A unique and striking position is taken by Adami and McCrae (*Text-book of Pathology*, 1914) . . . They are impressed with the mechanical relationships of the appendix and the large bowel in man as an erect animal. 'It is the appendix,' they hold, 'that is the hydrostatic agent initiating peristalsis in the large gut.' These writers maintain that, when the weight of the column of feces forming in the colon reaches a certain point, its distending force, acting on the appendix walls below, originates muscular contractions, which spread directly into the cecum and so start the forward movements of its contents. Adami and McCrae further thought that 'such a view explains constipation in the bedridden, in whom this gravitational influence of the contents of the ascending colon can have little effect; it explains the normal tendency to empty the bowels, either shortly after rising, and assuming the erect position, or after the first meal when stimulating peristalsis of the small bowel has driven extra contents into the cecum and so increases the load; it explains the constipation that follows some interval removals of the appendix.' 'Appendical constipation' was a special point in their proof 'through lack of initiation of colonic peristalsis, either from inflammation or other obliteration of the lumen of the appendix or operative removal of the same.' At the time my comment was 'One sympathizes with their effort to prove the hydrostatic function of the appendix and accepts the phenomenon offered but must feel some doubt concerning the sole agency of the appendix in producing the results.'"

I also called attention to a practically identical theory elaborated by Dufour (*Presse méd.*, May 12, 1890). "He felt that the appendix plays a great part in provoking a desire for defecation independent of reflexes concerned in the act. According to his view inflammation of the appendix disturbs its function by immobilizing the bowel instead of aiding its movements; while even without infection an appendix which is too movable excites the peritoneum and gives rise to hyperperistalsis with colicky pains. In the former condition constipation would be the rule and in the latter, alternating diarrhea."

While these hypotheses may seem unimportant and to some impossible of acceptance, my clinical experience during the past few years appears to confirm definitely the observations of Adami and McCrae, whose remarks I have reason to believe, were reprinted for the first time in my book. At any rate I cannot resist the impulse to suggest that discussion of the question may have some practical value. A paper by me, bearing on the subject, will appear shortly in the *Southern Medical Journal*.

HUBERT A. ROYSTER, M.D., Raleigh, N. C.

Medical Examinations and Licensure

COMING EXAMINATIONS

STATE AND TERRITORIAL BOARDS

Examinations of state and territorial boards were published in THE JOURNAL, May 15, page 1739.

NATIONAL BOARD OF MEDICAL EXAMINERS

NATIONAL BOARD OF MEDICAL EXAMINERS: *Parts I and II.* June 21-23 and Sept. 13-15. Ex. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

SPECIAL BOARDS

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY: *Oral examinations for Group A and B applicants* will be held in Philadelphia, June 7-8. Sec., Dr. C. Guy Lane, 416 Marlboro St., Boston.

AMERICAN BOARD OF INTERNAL MEDICINE: *Practical examination* will be given at Philadelphia in June. *Written examination* will be held in different centers of the United States and Canada in October. Chairman, Dr. Walter L. Biering, 406 Sixth Ave., Rm. 1210, Des Moines.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: *Practical, oral and clinical examinations for Group A and B applicants* will be held at Atlantic City, N. J., June 7-8. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh (6).

AMERICAN BOARD OF OPHTHALMOLOGY: Philadelphia, June 7, and Chicago, Oct. 9. *All applications and case reports, in duplicate, must be filed at least sixty days before the date of examination.* Sec., Dr. John Green, 3720 Washington Blvd., St. Louis, Mo.

AMERICAN BOARD OF ORTHOPAEDIC SURGERY: Atlantic City, N. J., June 8. Sec., Dr. Fremont A. Chandler, 6 N. Michigan Ave., Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY: Philadelphia, June 7-8. Sec., Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.

AMERICAN BOARD OF PATHOLOGY: Philadelphia, June 7-8. Sec., Dr. F. W. Hartman, Henry Ford Hospital, Detroit, Mich.

AMERICAN BOARD OF PEDIATRICS: Atlantic City, N. J., June 6, Sec., Dr. C. A. Aldrich, 723 Elm St., Winnetka, Illinois.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY: Philadelphia, June 2. Sec., Dr. Walter Freeman, 1028 Connecticut Ave., Washington, D. C.

AMERICAN BOARD OF RADIOLOGY: Atlantic City, N. J., June 4-6. Sec., Dr. Byrl R. Kirklin, Mayo Clinic, Rochester, Minn.

AMERICAN BOARD OF SURGERY: *Part I (written)*, Sept. 20. Sec., Dr. J. Stewart Rodman, 225 S. 15th St., Philadelphia.

AMERICAN BOARD OF UROLOGY: *Oral examination.* Minneapolis, June 25-26. Sec., Dr. Gilbert J. Thomas, 1009 Nicollet Ave., Minneapolis.

Arizona January Examination

Dr. J. H. Patterson, secretary, Arizona State Board of Medical Examiners, reports the written examination held in Phoenix, Jan. 6-7, 1937. The examination covered 10 subjects and included 100 questions. An average of 75 per cent was required to pass. Six candidates were examined, all of whom passed. Twenty-one physicians were licensed by reciprocity. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
University of Colorado School of Medicine.....	(1935)		79.9

Book Notices

Lectures on Embolism and Other Surgical Subjects. By Gunnar Nystrom, M.D., Professor of Surgery, University of Uppsala, Sweden. The Abraham Flexner Lectures, Series Number Four. Published for Vanderbilt University. Cloth. Price, \$3. Pp. 213, with 22 illustrations. Baltimore: Williams & Wilkins Company, 1936.

The Abraham Flexner lectureship was established in 1927 at Vanderbilt University School of Medicine. An adequate endowment was provided, the income from which was to be used to secure as lecturer, at intervals of two years, some eminent physician or scientist, who remains biennially in residence for a period of two months and becomes associated with the leading personnel and students. The fourth lecturer in this series, Prof. Gunnar Nystrom, gave a number of informal lectures in the wards, operating rooms and clinics. Only five of these have been included in the present volume.

The subject of the first lecture is embolism of the arteries of the extremities and its treatment. He not only relates his extensive personal experience (thirty-five cases) but has collected and analyzed the entire Swedish material, which because of its size and of its accurate follow up has served as a model for the rest of the world. Especially valuable are the figures of Strombeck, who followed sixty-one patients after their discharge from the hospital with restored circulation. He found that three fourths of these patients were alive after one year, half of them after three years, one third after five years and one eighth ten years after embolectomy. The great modesty of the author in describing his own contributions to the technic of the operation is apparent throughout the volume.

In the second lecture, pulmonary embolism and its surgical treatment are discussed. Here again the author is known as a pioneer in the field. A number of interesting charts are presented, some of them never published before, on the increasing frequency of embolism in the Uppsala clinics, on its relation to the increase in the age of surgical patients, on the number of deaths from private and public wards, and on the difficulties of preoperative diagnosis. Many important technical points are discussed. Real progress in this field can be expected when the causes of thrombosis and the methods of its prevention have become better understood.

The third lecture deals with Swedish experiences in combating appendicitis. He touches here on all the controversial points that are now agitating the surgeons of this country. In the Uppsala clinic the mortality from suppurative peritonitis has decreased from 20 per cent for the cases between 1888 and 1907 to 3.9 per cent from 1912 to 1918. In an enlightening table he shows that in 1934 operations were performed in 71 per cent of all cases within one day of the attack, in 85 per cent within five days and in 7 per cent more than three days after the attack. X-ray examination, with and without contrast enemas, has been used extensively in his clinic. In fact Hugo Laurell, roentgenologist at Uppsala, has made important contributions in this field. With regard to the Ochsner treatment of peritonitis, Nystrom, together with the other Scandinavian surgeons, believes that all cases of diffuse peritonitis due to appendicitis require immediate operation unless the patient is in a dying condition. His arguments, especially when he presents the data of Bauer of Malmo, are truly impressive. The author has also noted an increase in the mortality of appendicitis in the last few years but points out that some of this is only apparent. He suggests a widespread education of the general public, an increased vigilance on the part of physicians, further improvements in diagnosis, earlier admissions to the hospital, and possibly the development of serologic methods to decrease mortality.

There is an obvious inference to be drawn from the first three lectures: the excellent undergraduate and postgraduate education of the Swedish physicians, their alertness in the diagnosis of emergencies, and their unwillingness to handle surgical emergencies that are beyond their skill and experience.

In the fourth chapter the author discusses the cytology of joint exudates as an aid to diagnosis. More than 400 exudates, mostly from the knee joint, have been examined. Purposely only a simple method has been employed, which might be used in hospital laboratories or in the office. A differential

count was made between polymorphonuclear cells and mononuclear cells of all kinds. Either a dry smear is stained with borax-methylene blue or citrated sediments are stained by Quensel's method (methylene blue, sudan red and cadmium chloride). This Swedish colleague of Nystrom has studied a number of pleural and peritoneal exudates with this method. Absence or a very low count of polymorphonuclear cells in a joint exudate is characteristic of a slight chronic irritation of mechanical nature. A high count of polymorphonuclear cells is characteristic of toxic irritation, produced by aseptic necrosis, foreign chemical substances or toxins produced by microorganisms. A moderate degree of polynucleosis (from 40 to 70 per cent) is characteristic of the vast majority of cases of tuberculous synovitis, but neither a marked mononucleosis nor a high polynuclear cell count excludes tuberculosis of the joint. In various other types of arthritis the percentage of polymorphonuclear cells decreases with the subsidence of the process.

Nystrom regards these studies merely as an attempt for a tentative orientation. Certainly this field, to which many American authors, such as Sabin, Cunningham and Keyes, have made important contributions, has not been generally known or utilized by the profession. It should stimulate further work.

In the last chapter the treatment of intracapsular fractures of the neck of the femur is discussed. Here again Nystrom brings up a much discussed subject. After a short, lucid historical review in which the rôle of American surgeons is adequately discussed, the author describes his present method of choice, which is the Johansson modification of the Smith-Petersen flanged nail, used for internal fixation. In a period of one and a half years, twenty-nine cases of medial fractures of the neck of the femur were treated by this method. There are important technical details meticulously described. The death rate was 6.9 per cent; with increasing experience and prolonging the time of rest in bed to from two to three months his results have been growing better. Excellent diagrams illustrate the close follow up of these cases. He believes that this method gives better results than any one previously used.

These five lectures are of general interest. While they discuss surgical subjects, the relationship of early proper diagnosis by the physicians to the superb performances of the Swedish school of surgery is obvious. Vanderbilt University must be congratulated for having secured first hand information by one of the leaders in Scandinavian surgery. The text has retained the original forceful, sometimes foreign but grammatically correct delivery of the lecturer. Illustrations and printing are excellent. This group of lectures is recommended to all interested in surgery or to those who would wish to know how modern surgical methods can decrease the mortality of their handicapped patients.

Lomboartrite e sciatica vertebrale: Saggio clinico. DI V. PUTTI. Paper. Price, 50 lire. Pp. 218, with 144 illustrations. Bologna: L. Cappelli, 1936.

This monograph on lumbar arthritis and vertebral sciatica is a welcome publication. The author's name assures the value of the book. It contains a compilation of the author's previous presentation on this subject, and much besides. The author presents the theory of pathogenesis and etiology especially from the anatomic and osteologic points of view and outlines a plan of treatment. The illustrations, consisting of line drawings and reproductions of photographs, roentgenograms and colored photomicrographs, are excellent and instructive. Some of the noteworthy features are the relationship of the vertebral architecture, form and alignment to the nerve roots. The book contains anatomic diagrams showing radiculitis, ganglionitis and neuritis. The author describes the cause of pain in sacralization of the fifth lumbar. Figure 8 is an interesting diagram of the relationship of two vertebrae, their intervertebral disks, the foramen and the interarticular joint. Figures 16, 17 and 19 show the relationship of the articular facets of the lumbar vertebrae and illustrate the anomaly of tropism, of which the author has written previously. The anatomic demonstrations of arthritis of the apophysis are exceedingly well done. Figures 27, 28, 29 and 30, the demonstration of marginal osteophytes, is unusually clear. Radiographic demonstration of apophyseal arthritis is shown in diagrammatic representation and is instructive. Vertebral contraction producing sciatic scoliosis is well

demonstrated and described. The motor and sensory disturbances are discussed. The author describes his method of treatment by the Bier baker, and treatment by means of immobilization in plaster, corsets and celluloid jackets. He discusses also the surgical treatment of arthrodrosis, apophysectomy and his operation for sacralization, which is beautifully illustrated.

Therapeutic Uses of Infra-Red Rays With a Chapter on the Treatment of Sinusitis by Radiotherapy. By W. Annandale Troup, M.C., M.D., Ch.B. With foreword by Sir William Willecox, K.C.I.E., C.B., M.D. Third edition. Cloth. Price, 10s. 6d. Pp. 151, with 28 illustrations. London: Actinic Press, Limited, 1936.

This small textbook consists of a description of the therapeutics of infra-red rays and describes sources, methods of detection, indications and technic of application. There are chapters on the combined use of infra-red and ultraviolet rays, the treatment of "acutely painful conditions," the treatment of "rheumatism and allied conditions," rheumatoid arthritis, sinusitis, paresis, sprains, and long standing infections. While the book presents much valuable information on infra-red radiation and purports to serve as a plea for greater use of this valuable therapeutic agent, there is an unfortunate tendency in it toward exaggeration and an acceptance of conjecture as fact which may defeat this purpose. Such statements as the following are certain to be questioned: that infra-red radiation is "certain to give immediate relief" in the treatment of neuralgia; that infra-red radiation relieves pain "by liberating the nerve endings which have been caught up in the abnormal deposits"; that the use of "a blue filter over a certain type of heat lamp will relieve pain on extraction of teeth"; that "rheumatic conditions get well without the application of any local treatment but by means of application of general ultraviolet irradiation alone"; that acute fibrositis and neuralgia "can almost invariably be relieved and cured if seen early enough by one infra-red treatment," and that the author has "never yet seen a case of Bell's (facial) paralysis that will not clear up entirely after six properly applied infra-red treatments." The reader gains the impression that the author has fallen into the practice of applying a certain dull routine of heat applications with various types of lamps of his own devising which elaborate far infra-red rays, and that it is his custom almost invariably to follow these infra-red applications by local applications of ultraviolet radiation and general exposures to ultraviolet rays. Insufficient stress is placed on the value of simple applications of luminous heat by means of some simple source of near infra-red radiation, such as the home made "baker." It is unfortunate that many books on various phases of physical therapy have been prepared with insufficient attention to scientific detail and to controlled clinical experiment. This work is a case in point. In his conclusion the author frankly states that he presents the book with "an acute realization of its limitations." Despite these limitations, some of which have been mentioned, the text does contain much valuable information, and if the reader will discount the apparent lack of scientific proof of the author's contentions he may still read the book with considerable profit.

Physiological Principles in Treatment. By Sir Walter Langdon-Brown, M.A., M.D., F.R.C.P., Consulting Physician to St. Bartholomew's Hospital, London, and Reginald Hilton, M.A., M.D., F.R.C.P., Physician in Charge of Out-Patients, St. Thomas' Hospital. Seventh edition. Cloth. Price, \$3. Pp. 308, with 4 illustrations. Baltimore: William Wood & Company, 1936.

The contents of this excellent book, which is something more of an applied physiology than a treatise on actual therapeutics, comprise the principles of organotherapy, vitamins and the deficiency diseases, mechanical factors in digestion and indigestion, gastric and intestinal digestion, the work of the liver, uric acid and renal calculi, albuminuria and the treatment of nephritis, glycosuria, insulin and ketosis, some aspects of heart disease, the vasomotor system in disease, the life history of the red blood corpuscle, cyanosis and dyspnea, and allergy and some allergic diseases. There is a small list of principal references and a sufficiently comprehensive index. For the present edition a large portion of the work has been rewritten and there have been some modifications in the general plan. Vitamins, for example, are presented immediately after hormones, and the mechanical side of digestion precedes the discussion of its chemical phases. The separate chapters formerly devoted to intestinal toxemia and the uric acid bugbear have finally been omitted, allowing for a much abbreviated consideration of these subjects

with the topics to which they are allied. The subject of ketosis is now properly included in the same chapter as diabetes. Of the new chapters on anemia and allergy, the former is by far the more acceptable. The book, though by no means exhaustively presenting any of the subjects which it includes, will certainly and deservedly continue to hold the esteem of those who wish from time to time to peruse in thoughtful vein a review of some of the topics of main interest in internal medicine. In passing, however, one cannot help remarking the peculiar use which the British cousin sometimes makes of our language—witness the following from the work under consideration, which on the whole is written with clarity and a distinctive feeling for the use and meaning of words: "He had attempted suicide, and his brother was almost mental."

Healthy Growth: A Study of the Influence of Health Education on Growth and Development of School Children. By Martha Crumpton Hardy, Ph.D., and Carolyn H. Hofer, M.A. Cloth. Price, \$3.50. Pp. 360, with 12 illustrations. Chicago: University of Chicago Press, 1936.

This is a reference book of extraordinary exhaustiveness. It represents an investigation carried out by the Elizabeth McCormick Memorial Fund in the public schools of Joliet, Ill. For the serious student of growth and development of the healthy child, it is a book that will repay long and serious study. The volume consists of a careful description of the composition of the group of children studied, a description of the medical examinations employed and chapters devoted to the various observations, such as physical growth and development, mental growth, educational achievement, school progress and success, interests and attitudes, behavior adjustment, and influences of a health education program. There is also an extended discussion of health appraisal of school children and the rôle of health as related to development during late childhood. The data are presented in numerous tables and graphs and are exhaustively discussed. The book is a fine example of practical research and should be of great value to those in the schools who are concerned with health as a factor in educational progress. Physicians, too, should find this book a valuable discussion of normal childhood and a measure, therefore, against which deviation can more readily be evaluated.

Introduction à la chirurgie génito-urinaire. Par E. E. Lauwers. Préface du P^r. Legueu. Paper. Price, 32 francs. Pp. 197. Paris: Masson & Cie, 1936.

This book fulfils the purpose for which it was written; viz., to outline to the medical student in a brief but comprehensive manner the entire field of urology. It is written with an aim to keep the student ever in mind of the physiologic and pathologic processes responsible for the symptoms produced. Emphasis is placed on diagnosis. Treatment, though briefly outlined, is left for larger and more comprehensive works. The divisions of the book are extremely interesting. Pathologic and physiologic subject matter with associated symptoms are segregated and each is discussed from the standpoint of its relation to the urinary tract as a whole. This eliminates the customary division of upper and lower urinary tracts and is much less confusing to the beginner. In short, this book would serve as an excellent basic guide or outline which, if supplemented by outside references, would assure a comprehensive urologic course for the medical student.

Stoffwechselkrankheiten und Vererbung. Von Prof. Dr. Friedrich Curtius, Leiter der erbpathologischen Abteilung der 1. medizn. Universitäts-Klinik der Charité Berlin. Staatsmedizinische Abhandlungen, 13. Herausgegeben von Ministerialdirektor Dr. A. Gütt, Ministerialdirektor Dr. G. Frey, Staatsrat Dr. L. Contl, und Stadt-Med.-Rat Prof. Dr. W. Klein. Paper. Price, 1.80 marks. Pp. 19, with 8 illustrations. Leipzig: Johann Ambrosius Barth, 1936.

This is apparently a reprint of a semipopular lecture on metabolic diseases and heredity, with particular reference to diabetes mellitus. It is one of a series of pamphlets published in the interests of "race hygiene." The author cursorily reviews the evidence for the influence of heredity on the incidence of diabetes and attempts to show that this same hereditary factor also predisposes to obesity, the arthritides and nervous disorders. He concludes that young persons with diabetes should be discouraged from marriage and that the mating of members of "diabetic families" should be strictly forbidden. A bibliography is appended in which the only non-German reference is a book by Joslin, not correctly titled and incompletely cited.

Les abcès du foie. Par P. Huard, professeur agrégé à l'Ecole d'application du Service de santé des troupes coloniales, chargé de cours d'anatomie à l'Ecole de médecine de Hanoï, et J. Meyer-May, chargé de cours de clinique chirurgicale à l'Ecole de médecine de Hanoï. Préface du Professeur A. Gosset. Paper. Price, 65 francs. Pp. 390, with 98 illustrations. Paris: Masson & Cie, 1936.

This monograph is a thorough discussion of all phases of abscess of the liver. The opening chapter deals with the statistics of abscess of the liver, followed by chapters on surgical anatomy, symptoms and differential diagnosis. The book includes a complete chapter on radiologic diagnosis and localization of the lesions. Two complete chapters are given to medical and surgical treatment, and short abstracts are given of more than 150 cases, with observations at necropsy in forty-three cases. An extensive bibliography forms part of the monograph. The work is well written and is a definite contribution to the subject of hepatic abscess.

Absorption from the Intestine. By F. Verzár, Professor of Physiology of the University of Basle. Assisted by E. J. McDougall, Ph.D. Cloth. price, \$9. Pp. 294, with 70 illustrations. New York, London and Toronto: Longmans, Green & Co., 1936.

In this excellent monograph on a difficult but important problem in biology and medicine, the description of the histology of the absorbing mucosa is followed by an outline of the methods used in investigation of the factors and forces of absorption, and the succeeding chapters give a brief and clear account of the facts so far known regarding the absorption of all possible substances from the stomach, small intestine and large intestine. The style is clear and concise. Of special importance may be mentioned the evidence that the adrenal cortical hormone plays an important part in the selective absorption of sugar from the intestine as well as in the intestinal absorption of fat. Some of the known factors in absorption that have so far seemed contrary to known physical and chemical factors seem to be brought into harmony with these principles by processes of resynthesis in the cells of the mucosa of large molecules from the smaller molecules absorbed. This produces a diffusion gradient from the lumen of the intestine into the cells. The monograph is a welcome addition to the scientific armamentarium not only in the research laboratory but also in the clinics dealing with gastro-intestinal disturbances.

Technique of the Love-Act: A Medical Contribution for the Advancement of the Sexo-Physiological Harmony in Marriage. By Doctor Douglas MacDougall. With Cabinet of Diagrams. Cloth. Price, \$3.50. Pp. 63. New York: Medical Press of New York, [n. d.].

Kama Sutra: The Hindu Science of Love. By Mallinaga Vagasyana. Translated from the Sanskrit by Sir Richard Burton. Introduction by Hanns Heinz Ewers. Cloth. Pp. 127, with illustrations by Mahlon Blaine. New York: Medical Press of New York, 1936.

These two volumes are promoted to the medical profession with lurid circulars sent direct by mail which give the impression that the volumes offer something extraordinary, titillating and forbidden. They are merely pamphlets bound in solid covers, poorly illustrated and poorly printed, and sold at an excessive price because of the nature of the material that they are alleged to contain. They are obviously not the type of books that are given to small children for their amusement and entertainment. Some may have considerable doubts as to their general distribution even among adults. They do contain suggestions for variation in the sex act and for rituals of excitation which may not occur to many unimaginative or inhibited individuals.

Roads to Health and Happiness. By Oscar C. Mueller. Cloth. Price, \$2. Pp. 137. New York: Prentice-Hall, Inc., 1936.

The author retired from the practice of law ten years ago and has since then given his attention to the business of living. In this volume he sets forth what he prefers to call "the results of his researches." It would be better to call his volume his observations and philosophy on life and those who live it. He discusses sixteen subjects, which include nostrums, insomnia, hobbies, divorce and the right to happiness. In the discussion on food the author is impressed with "acidosis," since he mentions it frequently and plays up the alkaline foods. He does not appear to be quite clear in his own mind on the meaning of many of the topics, since he uses phrases such as "blood cleanser" in discussing leafy vegetables. In the chapter on

tobacco the statement that "tobacco stunts growth" is the only one to which the purist will object. The author is at his best in his observations on divorce, especially those which deal with the legal phases. The physician may find this book of interest because of the many quotations from people of all the ages including the modern radio and cinema comedians. The paragraphs on health have been said before and often better, yet not all authors are as meticulous as this one in crediting sources of information.

Fille ou garçon. Comment avoir fille ou garçon. Diagnostic précoce de la grossesse. Comment connaître le sexe avant la naissance. Par le Docteur Jules Regnault. Paper. Price, 18 francs. Pp. 299, with illustrations. Paris: Editions Médicis, 1936.

This book combines the ancient history, the folklore, and the scientific and personal observation phases of the problems of predetermination of sex of offspring, early diagnosis of pregnancy, and the prenatal determination of the sex of the unborn child. The work is interesting from a historical point of view and is written in a humorous vein as though the author were sitting back with his tongue in his cheek. The part of the book dealing with pregnancy diagnosis is fairly complete, and in the discussion of methods of diagnosis of the sex of the unborn child all the diagnostic apparatus available for such diagnosis, including the Abrams machine, are described. As a scientific book for the physician's education this book would not serve: as a humorous quasiscientific bit of reading it may prove to be of interest.

A Text-Book of Inorganic Pharmaceutical Chemistry for Students of Pharmacy and Pharmacists. By Charles H. Rogers, D.Sc., Dean of the College of Pharmacy and Professor of Pharmaceutical Chemistry, University of Minnesota. Second edition. Cloth. Price, \$7. Pp. 721, with 55 illustrations. Philadelphia: Lea & Febiger, 1936.

True to its title, this volume discusses inorganic pharmaceutical chemistry. It is based on the U. S. Pharmacopeia and the National Formulary except for arrangement. In addition, the methods of commercial manufacture are described. It is nicely printed and bound. As a reference book it is excellent. As a textbook it may be differently considered. The book is a compendium of information that is easily obtained from the Pharmacopeia, the National Formulary and other books. It is more worth while to teach generalities, laws and reasons for facts than to teach masses of information as easily found and understood as is much of the information found in this book.

The Boy's Book of Strength. By C. Ward Crampton, M.D. Cloth. Price, \$2. Pp. 257, with illustrations. New York & London: Whittlesey House, McGraw-Hill Book Company, Inc., 1936.

Dr. Crampton has written a book that almost every boy between the ages of 8 and 15 can read with pleasure and profit. It is a simple and practical program of health management which seeks to coordinate all the social agencies that touch on the youth's daily life. The style of the book is direct and engaging and cannot help but elicit the reader's interest. The author's long experience with youth activities is admirably reflected in the organization of his text. The information is sound, stimulating and written in the boy's language. Each chapter is concise, explicit and well illustrated by diagrams. The book should be part of the library of every growing boy.

Tentatives opératoires dans le traitement de certaines psychoses. Par Egas Moniz, professeur de neurologie à la Faculté de médecine de Lisbonne. Paper. Price, 40 francs. Pp. 248, with 39 illustrations. Paris: Masson & Cie, 1936.

The author, who is known for his arterial encephalography, has ventured again into a radical diagnostic and therapeutic procedure. On the assumption that certain psychoses are due to congenital malformations of the frontal association fibers, he attempts to destroy these abnormal fibers by injecting alcohol into the white matter of the frontal lobes. He avoids producing paralysis or aphasia. His results have been encouraging to him, although, as he states, the patients are not always intellectually the same after the treatment. A good deal more work must be done experimentally before the procedure can be utilized in this country. The basis for the treatment is incomprehensible to us and we should demand much more empirical data before even thinking of using this extremely radical procedure.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Optometry Practice Acts: Advertising Fixed Prices; Injunction to Restrain Advertising.—Three registered optometrists and the Michigan Society of Optometrists, on behalf of themselves and duly registered optometrists, filed a bill to enjoin the Buhl Optical Company, a Michigan corporation with its offices at Pittsburgh, from advertising the prices of glasses and from using the statement "Scientific eye examination included," or any statement of like effect in its advertisements, such advertising being proscribed by the optometry practice act of Michigan. The trial court issued a temporary injunction and the optical company appealed to the Supreme Court of Michigan.

The difficulty, said the court, with the optical company's entire position is its belief that optometry is merely an incident to its corporate merchandising business. It overlooks the fact that optometry is a science devoted to the measurement of the accommodation and refractory powers of the eye without the use of drugs. The legislatures of the several states have recognized that the proper practice of this profession is of the most vital importance to the public and have provided not only for the licensing of optometrists after examination but for regulating the practice of the profession. The advertising of the sale of glasses with optometrical service at a price certain, continued the court, is apt to be used as a lure and bait to the unwary and as a means of deception to those who are attracted by a seemingly low price without considering the degree of skill involved. It tends to promote unfair competition against those skilled in the profession. The "barker" and others who make their livelihood out of human gullibility cannot apply their talents to human eyesight without serious consequences. The legislature of Michigan undoubtedly had these evils in mind when it adopted the optometry practice act, and reasonable statutory regulation of advertising involving professional services is proper where, in the absence of such legislation, great evils will follow.

The optical company contended, apparently, that since it employed only licensed physicians and surgeons, the optometry act did not apply to it because of a proviso in the act exempting physicians and surgeons from its provisions. But, said the court, the Buhl Optical Company is not a physician or surgeon, despite the fact that it may hire only physicians and surgeons to do its optometric work. The injunction granted by the trial court was not "pointed at a medical doctor" but at a "corporation engaged in the sale of merchandise . . . who maintains . . . in connection with said merchandising business, an optometric business." The court here referred to the case of *Eisensmith v. Buhl Optical Company*, 115 W. Va. 776, 178 S. E. 695, in which the company made a futile attempt to circumvent the law by using a physician as a subterfuge. The company in the present case further contended that the restriction on advertising resulted in an unreasonable classification and deprived it of property without due process of law. The only objection, countered the court, with even a semblance of merit is the claim that the statute does not prevent physicians or unregistered optometrists from advertising that which others in the same class are forbidden. The objection that the prohibition would not apply to unregistered optometrists is not a fatal one, the court pointed out, as the act provides other penalties for the failure to register, and it is not necessary to make the prohibition against advertising applicable to one who is practicing optometry illegally. Further, the various laws regulating medical advertising have been deemed sufficient to cover the advertising of physicians practicing optometry.

The further contention was made that the plaintiffs did not have sufficient property interest in the subject matter to entitle them to an injunction and that the injunctive process may not be used for the purpose of enjoining a crime. Suit may be brought by persons, said the court, engaged in a profession or business to enjoin unfair trade and practice which would be

injurious to their interests, and the fact that such practices are punishable by criminal penalties is immaterial. The action of the trial court in granting the injunction was sustained.—*Seifert v. Buhl Optical Co. (Mich.)*, 268 N. W. 784.

Wills: Alcoholism in Relation to Testamentary Capacity.—The habitual use of intoxicating liquor to excess, said the district court of appeal, third district, California, may result in permanent insanity. To constitute insanity, however, more than dipsomania must be shown. It must be a condition of fixed mental unsoundness, and insanity cannot be presumed on proof merely of habitual drunkenness however excessive or long continued. The fact that a testator may have been under the influence of intoxicating liquor at the time he made his will does not invalidate the instrument unless he at that time had no independent comprehension of what he was doing. The intoxication of the testator, assuming it to have been established on the day of execution of his will, must have been of such a degree as to deprive him of judgment while executing the will. It must affirmatively appear that the testator was so far under the influence of liquor at the time of the execution of the will that he was incapable of comprehending the nature of his act, the extent of his property, and those who had a claim on his bounty.

The presumption is that a person is sane. It devolves on the contestants of a will to establish, not only that the testator was of unsound mind, but that at the very time he executed his will he did not have the mental capacity to know the nature of his act or the nature or situation of his property; the natural objects of his bounty, and how they would be affected by the will. On the contest of a will on the ground that the deceased was of unsound mind, it is the mental condition of the testator at the time of the execution of the will that is important. Evidence as to mental condition before or after the execution of the will is important only so far as it tends to show the mental condition at the time of the execution of the instrument.—*In re Smethurst's Estate: Smethurst v. Smethurst (Calif.)*, 59 P. (2d) 830.

Workmen's Compensation Acts: Hemiplegia Attributed to Mercurial Poisoning.—The claimant, aged 38, contracted mercurial poisoning during the course of his employment as a hatter. A hemiplegic condition developed in his right side for which the compensation commissioner allowed compensation. After the superior court had affirmed that award, the employer appealed to the Supreme Court of Errors of Connecticut.

The question before the court was whether the hemiplegia from which the claimant admittedly was suffering and by which he admittedly was incapacitated resulted from mercurial poisoning or was due to a congenital aneurysm as contended by the employer. While a paralysis resulting from mercurial poisoning, said the court, is very rare, it has been known to occur. There is no objective sign to distinguish a ruptured blood vessel resulting from aneurysm and a ruptured blood vessel resulting from mercury. An aneurysm, however, in a man of 38 years of age is a rarity. One of the witnesses for the claimant who had had much experience in cases of mercurial poisoning and who had attended and observed the claimant over a long period of time testified that in his opinion the hemiplegia was due to mercury. He found nothing in the claimant's physical condition to cause hemiplegia. Another witness for the claimant stated that, from his examination of the claimant and his experience with mercurial poisoning, the hemiplegia was due to mercurial poisoning. Physicians who testified for the employer were of the opinion that the claimant's condition was due to congenital aneurysm, basing their opinions on the fact that they had found in medical literature no authentic cases in which a paralysis of the type from which the claimant was suffering resulted from mercurial poisoning.

In the opinion of the Supreme Court of Errors, the conclusion reached by the compensation commissioner was supported by the opinions of qualified experts who stated plainly and definitely that in their professional opinion mercurial poisoning was the superinducing cause of the claimant's disability. Although the case was an unusual one, the court said, it cannot be said that the evidence of these witnesses was such that a rational mind could not believe it. The decision of the com-

missioner being based on conflicting testimony, the court felt disinclined to interfere with it. The award in favor of the claimant was, in effect, affirmed.—*Manack v. George McLachlan Hat Co. (Conn.)*, 186 A. 487.

Evidence: Admissibility of Roentgenograms for Purpose of Comparison; Right of Physician to Refresh Memory from Hospital Records.—Roentgenograms of the normal pelvic bones of a female two years older than the injured female plaintiff, said the Supreme Court of Minnesota, are admissible in evidence for the purpose of comparing them with roentgenograms of the latter's fractured pelvis bones. An attending physician, in testifying relative to the temperature and pulse of a patient, may refresh his memory by consulting the patient's hospital record which he had previously identified.—*Draxten v. Brown (Minn.)*, 267 N. W. 498.

Medical Practice Acts: Drugless Healing as Practice of Medicine.—Persons who desire to practice any branch of the healing art in Pennsylvania, even though that branch does not embrace the administration of drugs, should by this time, said the superior court of Pennsylvania, be able to understand that they cannot lawfully engage in such practice until they have complied with the requirements of the medical practice act. The judgment of the trial court convicting the defendant of practicing medicine and surgery without a license was consequently affirmed.—*Commonwealth v. Mollier (Pa.)*, 186 A. 757.

Malpractice: Ophthalmia Neonatorum in Relation to Failure to Use Prophylactic as Required by State Health Regulations.—The defendant, a physician, attended the birth of the plaintiff's baby. Four days thereafter the baby developed an infection of the eyes, which eventually resulted in total blindness of the right eye and impairment of vision in the left eye. Suit was instituted against the physician, attributing the infection and its results to his negligence in caring for the child at and after birth. In the trial court the jury disagreed but the court, on motion of the defendant, dismissed the case on the ground that the evidence was insufficient to sustain a verdict for the plaintiff. Thereupon the plaintiff appealed to the Supreme Court of Washington.

Ophthalmia neonatorum, said the court, is an infection in the eyes of the new-born and although the term may be applied to any infection, it is generally accepted as indicating the presence of gonococci. As a precautionary measure, the state health regulations require that at birth a solution of silver nitrate or mild protein silver [argyrol] shall be put in the infant's eyes. When the prophylactic is used, ophthalmia neonatorum develops in only one case in a thousand; when it is not used, the infection develops in 10 per cent of the cases. In the present case the prophylactic was not used. According to the evidence, on the afternoon of the third day the mother noticed that the eyelashes of the baby's left eye were covered with "matter" and stuck together. The following day she spoke to the physician about the condition and he told her that he would take care of the child's eyes, expressing the opinion that he thought the condition was the result of a cold. The condition gradually grew worse, the purulent discharge increasing day by day. When the mother left the hospital, a nurse advised her to put one drop of 5 per cent mild protein silver [argyrol] in the baby's eyes twice a day and wash them every three hours with a solution of boric acid. Subsequently the right eye became infected and the discharge from the eyes became streaked with blood. Finally the defendant advised the parents to take the child to an eye specialist, who caused laboratory tests to be made of the discharge from the eyes. The laboratory reports failed to show the presence of gonococci. This specialist diagnosed the condition as conjunctivitis and attributed it to closure of the nasal ducts.

There was no direct testimony that the child was suffering from a gonorrheal infection. A number of experts testified that the treatment given by the parents was proper and adequate for the condition described. This testimony, the court thought, was predicated on the assumption that the infection was not gonorrheal. While the laboratory reports on the smears taken from the eyes indicated that no gonococci were present, this fact, the court said, did not eliminate a diagnosis of gonorrheal infection if a clinical examination so indicated.

The failure to administer the prophylactic constituted negligence, viewed either as a violation of the state health regulations or as a departure from accepted practice. Whether the infection was gonorrheal and whether it was the proximate result of such negligence were for the jury to say. In the opinion of the Supreme Court, therefore, the trial court erred in dismissing the case and it was remanded to the trial court for further proceedings.—*Jordan v. Skinner (Wash.)*, 60 P. (2d) 697.

Society Proceedings

COMING MEETINGS

- American Medical Association, Atlantic City, N. J., June 7-11. Dr. Olin West, 535 North Dearborn St., Chicago, Secretary.
- American Academy of Pediatrics, New York, June 3-5. Dr. Clifford G. Grulee, 636 Church St., Evanston, Ill., Secretary.
- American Academy of Tuberculosis Physicians, Atlantic City, N. J., June 7-8. Dr. Arnold Minnig, 638 Metropolitan Bldg., Denver, Secretary.
- American Association for the Study and Control of Rheumatic Diseases, Atlantic City, N. J., June 7. Dr. Loring T. Swaim, 372 Marlborough St., Boston, Secretary.
- American Association for the Study of Goiter, Detroit, June 14-16. Dr. W. Blair Mosser, 133 Biddle St., Kane, Pa., Secretary.
- American Association for Thoracic Surgery, Saranac Lake, N. Y., May 31-June 2. Dr. Richard H. Meade Jr., 2116 Pine St., Philadelphia, Secretary.
- American Association of Genito-Urinary Surgeons, Quebec, Canada, June 14-16. Dr. Henry L. Sanford, 1621 Euclid Ave., Cleveland, Secretary.
- American Bronchoscopic Society, Atlantic City, N. J., June 2. Dr. Lyman Richards, 319 Longwood Ave., Boston, Secretary.
- American Dermatological Association, Sky Top, Pa., June 3-5. Dr. Fred D. Weidman, 1930 Chestnut St., Philadelphia, Secretary.
- American Gastro-Enterological Association, Atlantic City, N. J., June 7-8. Dr. Russell S. Boles, 1901 Walnut St., Philadelphia, Secretary.
- American Gynecological Society, Swampscott, Mass., May 31-June 2. Dr. Richard W. TeLinde, 1201 N. Calvert St., Baltimore, Secretary.

- Maine Medical Association, Belgrade Lake, June 20-23. Miss Releah Gardner, 22 Arsenal St., Portland, Secretary.
- Massachusetts Medical Society, Boston, June 1-3. Dr. Alexander S. Begg, 8 The Fenway, Boston, Secretary.
- Medical Library Association, Richmond, Va., May 23-26. Miss Janet Doe, 2 East 103d St., New York, Secretary.
- Medical Women's National Association, Atlantic City, N. J., June 6-8. Dr. F. S. Fetterman, 7047 Germantown Ave., Philadelphia, Secretary.
- Montana Medical Association of Great Falls, July 13-14. Dr. E. G. Balsam, 208½ North Broadway, Billings, Secretary.
- National Tuberculosis Association, Milwaukee, May 31-June 3. Dr. Charles J. Hatfield, 7th and Lombard Sts., Philadelphia, Secretary.
- New York Medical Society of the State of, Rochester, May 24-26. Dr. Peter Irving, 2 East 103d St., New York, Secretary.
- Pacific Northwest Medical Association, Great Falls, Mont., July 8-10. Dr. C. W. Countryman, 407 Riverside Ave., Spokane, Wash., Secretary.
- Rhode Island Medical Society, Providence, June 2-3. Dr. Guy W. Wells, 124 Waterman St., Providence, Secretary.
- Society of Surgeons of New Jersey, Englewood, May 26. Dr. Walter B. Mount, 21 Plymouth St., Montclair, Secretary.
- South Dakota State Medical Association, Rapid City, May 24-26. Dr. John F. D. Cook, Langford, Secretary.
- Vancouver Medical Association Summer School, Vancouver, B. C., June 22-25. Dr. J. R. Naden, 203 Medical-Dental Bldg., Vancouver, Secretary.
- West Virginia State Medical Association, Clarksburg, May 24-26. Mr. Joe W. Savage, Public Library Bldg., Charleston, Executive Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

Alabama Medical Association Journal, Montgomery

G: 293-316 (March) 1937

- Some Recent Advances in Orthopedic Surgery. S. R. Terhune, Birmingham.—p. 293.
Diagnosis and Treatment of Pain About the Face and Head: Comprising Major Types of Neuralgia. W. M. Craig, Rochester, Minn.—p. 296.
Notes on High Eosinophil Counts in Arsphenamine Poisoning. G. Walsh and C. S. Stickley, Fairfield.—p. 299.
Skeletal Traction. F. L. Chenault, Decatur.—p. 300.
Hay Fever in Alabama: I. The Flora of Alabama. C. K. Weil, Montgomery.—p. 302.
Fractures of Lower End of Tibia and Fibula. C. L. Guice, Gadsden.—p. 305.

American Journal of Hygiene, Baltimore

25: 187-420 (March) 1937. Partial Index

- Studies on Oocyst Production in Avian Coccidiosis: I. Dilution Count Technic. D. C. Boughton, Princeton, N. J.—p. 187.
Id.: II. Chronic Isosporan Infections in Sparrow. D. C. Boughton, Princeton, N. J.—p. 203.
*Studies on Yeastlike Organisms Isolated from Mouths and Throats of Normal Persons. Ramona L. Todd, Minneapolis.—p. 212.
Experience in Vaccinating Against Yellow Fever with Immune Human Serum and Virus Fixed for Mice. W. A. Sawyer, New York.—p. 221.
*Study of Objective Efficacy of Liver Therapy in Pernicious Anemia Based on Recorded Mortality Data. A. H. Sellers, Toronto.—p. 259.
Application of Paired Feeding Method to Studies of Chemical Changes in Blood of Dogs Following Suprarenalectomy. H. G. Day, H. D. Kruse and W. M. Firor, Baltimore.—p. 269.
Effect of Direct Animal Passage on Pathogenicity of Endamoeba Histolytica for Kittens. H. E. Meleney and W. W. Frye, Nashville, Tenn.—p. 313.
Localization of Trichinella Spiralis in Muscle of Its Host. C. H. Scheiffey, Rochester, Minn.—p. 349.
Subcutaneous Smallpox Vaccination with Bacteria Free Vaccine. E. Gallardo and J. Sanz.—p. 354.

Yeastlike Organisms in Mouths of Normal Persons.—Todd found, by culture studies, that 14 per cent of 1,000 normal individuals harbored *Monilia albicans*. In 7 per cent the organism was present in both the mouth and the throat, in 3.1 per cent the organism was obtained only from the mouth, and in 3.9 per cent only from the throat. There was a higher incidence in women, as 18.2 per cent of 527 women yielded the organism, while it was present in only 9.3 per cent of 473 men. Of the serums tested from 1,150 normal persons 259, or 22.5 per cent, agglutinated *Monilia albicans*, but only thirty-five reactions were of a titer of 1:160 or above. Results showed that agglutinins for *Monilia* were present in the serums of 30.4 per cent of 533 women and 15.7 per cent of 617 men. There is a relationship between a high titer of agglutinins in the serum and the presence of *Monilia albicans* in the mouth and throat.

Efficacy of Liver Therapy in Pernicious Anemia.—Sellers investigated objectively the extent of the prolongation of life of persons dying of pernicious anemia since 1926. Despite the wide differences in mortality from pernicious anemia throughout the world an abrupt decline is noted in a group of widely separated representative countries. The trends in mortality in each instance are remarkably alike. An abrupt alteration of the trend of mortality from pernicious anemia occurred in 1927 coincident with the general introduction of liver therapy as specific treatment in this disease. The low level of mortality reached in 1927 and 1928 has in general been well maintained. Reduction in mortality from pernicious anemia has been most marked at young ages but has occurred in all age groups up to 70 years.

Factors Influencing Quantitative Measurement of Roentgen-Ray Absorption of Tooth Slabs: VII. Sensitometric Factors. H. C. Hodge, R. B. Wilsey, G. Van Huysen and S. L. Warren, Rochester, N. Y.—p. 385.

Skeletal Changes in Anemias.—The earliest lesion of the skull that Caffey found in twenty-one cases of erythroblastic anemia studied roentgenologically was thickening of the lower frontal squamosa. Radial striations developed first in the anterior portion of the parietal bones near the sagittal suture. The sequence of thickening of the calvarium and the sequence of striation of the calvarium are described. The frontal bone was the site of the earliest and most marked thickening. The earliest lesion in the long bones was dilatation of the medullary canals with simultaneous atrophy of cortical bone and of cancellous bone. Reticulation in the long bones appeared several months after the first changes were apparent. The late skeletal changes in a long-standing severe case were osteosclerotic due to late increase in cancellous bone. Two mild cases with late onset had no diagnostic changes in the skeleton. No significant skeletal changes were found in the long bones of fifteen cases of sickle cell anemia. Ten cases showed thickening of the calvarium similar to that in erythroblastic anemia. Vertical striations of the skull were not present in any case. In contrast to erythroblastic anemia, the parietal bones showed more marked involvement than the frontal. Also in six cases of chronic hemolytic icterus no significant changes were seen in the long bones. Two cases showed thickening and striation of the calvarium similar to that of erythroblastic anemia. In both cases the parietal bones were more involved than the frontal. No roentgen or clinical signs of premature synostosis of the cranium were present in this group of six cases.

Radium Poisoning.—Evans describes a technic for determining the radium content of a living person which is many times more sensitive than former methods and permits the quantitative detection of a small fraction of a "fatal dose." No postmortem analyses, phantoms or cadavers are involved. By electrical detection of the radiations emitted by radioactive substances, these elements may be quantitatively determined in amounts millions of times smaller than would be possible by chemical analysis. In some cases the penetrating gamma radiation emitted from a material containing radioactive substances permits analysis for these substances without the necessity of removing a sample, it being sufficient to place a sensitive gamma-ray detector in the neighborhood of the material to be examined. When smaller quantities (order of a million millionth of a gram) of radium are involved a discrete sample is necessary. Part (about 45 per cent in chronic cases) of the total amount of radium stored in the skeleton and tissues of a victim of radium poisoning gives rise to radon (radium emanation) in the expired breath. The radon, and consequently the amount of radium producing it, is determined by electrical tests on the expired air. The remainder of the body radium is determined by the gamma rays from its decay product, radium C. A general method for determining the amount of a gamma-ray emitting radioactive substance in a closed and inaccessible container is described. Through its application to the feeble gamma rays observed a meter from

a victim of radium poisoning, the radium C content of the patient has been determined. The method corrects for scattered gamma rays, internal absorption of gamma rays by the body itself and for the nonuniform distribution of radium in the various bones and tissues. The quantum counters are then directly calibrated for rapid measurement of the radium C content of other human victims in terms of the observed gamma radiation near the spine, hips, jaw or chest. The rate of loss of radium by the patient is directly measured by radium analyses of the feces and urine; for chronic cases 0.005 per cent daily is eliminated, 91 per cent in the feces and 9 per cent in the urine. The mobilization of radium within the body is studied by radon analyses of specimens of alveolar air. Simple gamma-ray examinations of patients will detect chronic radium poisoning five or ten years before any clinical symptoms appear.

Analyses of Blood and Cerebrospinal Fluid in Schizophrenia.—Katzenelbogen reports his observations obtained in a study of nineteen different constituents in the cerebrospinal fluid of twenty schizophrenic or parergastic patients. These data were derived from special investigations of blood and cerebrospinal fluid withdrawn simultaneously and analyzed. As far as could be established in tracing the beginning of serious disorders before hospitalization, the duration of the psychoses ranged between three months and fifteen years. The main clinical facts show the presence of manifold parergastic reactions,

with delusions of persecution and habit deterioration standing out conspicuously as to frequency. In only three of the twenty patients were values for all the nineteen constituents determined for both blood and cerebrospinal fluid within normal limits. In each of the remaining seventeen patients, one or another component proved to be abnormal either in the blood or in the cerebrospinal fluid or in both. With regard to frequency, the potassium content was increased in eight cases, the lactic acid content in seven, the cholesterol content of the cerebrospinal fluid in seven, the globulin content in the blood in four, the amino acid nitrogen in four, the total protein and globulin in the cerebrospinal fluid in two and the total protein and albumin in the cerebrospinal fluid in two, while the calcium content was decreased in the cerebrospinal fluid in three. The value for free cholesterol in the blood was low as compared with that for total blood cholesterol in two cases. The uric acid content of the blood was decreased in one case.

Archives of Ophthalmology, Chicago

*Optic Encephalomyelitis: Report of Case. J. Rosenbaum, Montreal.—p. 694.
Scleromalacia Perforans: Report of Case. S. P. Oast, New York.—p. 698.
Organization of the Department of Ophthalmology of Long Island College of Medicine. J. N. Evans, Brooklyn.—p. 702.

Optic Encephalomyelitis.—Rosenbaum's patient with optic encephalomyelitis was an otherwise healthy woman, aged 34. There were rapid loss of vision of the left eye, with no recovery, and loss of vision of the right eye, with partial recovery. Paralysis of the right leg and of the abdominal muscles followed about four months after the onset of the disease in the optic pathway. The course of the ocular phenomena remained obscure until the definite signs presented themselves in the spinal cord and thus completed the picture of optic encephalomyelitis. Marked leukopenia was present during the entire course of the illness.

Extravasating Dye as Measure of Skin Permeability to Bacterial Invasion.—The subject of disinfection of the skin divides itself into surgical disinfectants and the disinfective power of the skin itself. It is with the latter aspect

that Pijoan and Wheeler are concerned. While results in the literature proved suggestive, they felt that the methods used did not afford a very exact evaluation of percutaneous bacterial invasion as an active process. They thus found it necessary (1) to measure the degree and presence of percutaneous bacterial invasion, (2) to determine how rapidly the self-disinfecting power is restored to the shaven skin and (3) to determine if shaving modifies the intracutaneous spread of bacteria. Their contention is that shaving increases the susceptibility of the skin to bacterial penetration, possibly owing to minute abrasions caused by the razor on the keratinized epithelium or to a defense process in the horny layer. It seems reasonable to suggest, on the bulk of evidence contributed by other investigators and by their experiments, that shaving before an operation should take place at least thirty hours previous to the incision. It is not denied that after an operation more bacteria penetrate the wound than the surrounding skin, even though freshly shaven, but they suggest that newly shaven skin is more likely to have pathogenic organisms lodged in the cutaneous tissues, and it is through these tissues that the initial incision is made. An azo dye, T-1824, employed intravenously delimits the area of bacterial invasion and inflammation by the blue stain it imparts to infected tissues.

The Progress of Medicine. A. J. Wood, St. Petersburg.—p. 433.
Application of Psychiatry to School and Business. W. C. McConnell, St. Petersburg.—p. 435.

Pruritus Without Primary Skin Lesions.—Mount defines pruritus as a disturbance of the nerve elements of the skin, a paresthesia. It is an anomaly of feeling, not dependent primarily on local lesions or changes or local irritations, and not denoting any increase or decrease of the normal sensations. Jacquet claims that an itchy area is in a state of prurigenous hyperesthesia and that following a prolonged scratching it goes into a state of hypesthesia. The etiologic factors producing itching of the skin may be divided into internal and external. The internal may occur by means of the nervous system or through the blood or lymph. The dependence on the psyche must be borne in mind therapeutically because it is sufficient to keep out of the patient's consciousness the fact that healing has already been accomplished. Granted that the sickness causing the itching has been cured, the pruritus may still torment the patient. He fears it, he thinks about it, he broods over it; in fact, it becomes the all-possessing idea and that is sufficient through psychic means to keep up the paresthesia which was set loose by somatic disturbances removed by this time. The physician must be keen enough, whenever possible, to charm away the suggestive influence by suggestion as well as by a firm assurance of the cure. Sometimes itching of the skin is due to organic changes in the central nervous system. Various central organic conditions have had pruritus associated with them. In itching by way of the hematogenous route there must be in the blood stream changes that alter the nerve endings in the skin, either the corpuscles of Vater and Meissner and the end knobs of Kraus or the free, fine, non-medullated fibrillae. There is a large group of cases in which the pruritus is due to a susceptibility of the skin to some external excitant. This excitant may be of the most varied type, for instance, a puzzling recurrent pruritus of the left cheek due to the wearing of a boutonniere, in this case an aster; the localized itching of the neck in women due to exposure following shingling and bobbing of the hair; a pruritus of the face coming each week and finally found to be

caused by a susceptibility to the colored sheet of the Sunday newspaper; the itching due to face powders, perfume itself or the odor of the latter. The causal differential diagnosis depends much on the type of pruritus. With a localized case, one certainly must seek an external irritant as the excitant. With a process involving the vulva or anus, fissures, hemorrhoids or gynecologic conditions must be excluded. Failure to examine the urine is inexcusable, as is also the failure to search for body parasites. With the generalized type, the causation may be drugs, one of the lymphomas, diabetes, focal infection, uricemia, or one of the variety of excitants which can be differentiated only by a careful study of the body liquids and the blood.

Correlation Between Food Dislikes and Food Allergy.

—In the objective as well as in the amnesic study, Vaughan and Pipes find that about one patient out of five will mention food dislikes that are subsequently found to be related to allergic reactivity. Furthermore, among the 20 per cent in which there is a correlation, many additional foods are mentioned in which there is no correlation. When foods mentioned instead of cases are considered, a much wider discrepancy is found. Among the major and the minor allergic persons of the amnesic group a total of 1,656 foods were mentioned that did not correspond as compared with a total of eighty-four foods that did correspond. In the objective group, foods that did not correspond were mentioned ninety-six times, as compared with seven foods that did correspond with positive skin reactions and seven that corresponded with borderline skin reactions. While foods disliked may be responsible for food allergy, this is not the rule, and foods disliked cannot be relied on as indicative of allergic sensitization. The one exception is those instances in which gastro-intestinal symptoms follow the ingestion of the allergenic food after such a short interval that the patient has himself recognized a relationship of cause and effect.

Streptococcus Salivarius.—Safford and his co-workers limited their study to 322 cultures of nonhemolytic streptococci isolated from human throats. The isolations were made by

the application of quantitative methods so as to limit the collection to the predominating types. *Streptococcus salivarius* was found to be the prevailing type and 290 of the cultures studied are believed to be typical of the species. The remaining thirty-two cultures varied somewhat from the type, but scarcely enough to be considered separate species in the light of present knowledge of the streptococci. *Streptococcus salivarius* may be readily differentiated from any of the clearly established species of the streptococci. A full description of the organism is given.

Bacteriolytic Power of Defibrinated Blood in Gonococcal Arthritis.—Spink and Keefer find that the whole blood from normal individuals is capable of destroying varying numbers of gonococci obtained from patients with infection. Strains of gonococci obtained from local lesions, such as urethritis, are often killed in larger numbers than are those derived from patients with arthritis. Destruction in vitro occurs by lysis and this is a function of the blood plasma and not of the polymorphonuclear leukocytes. During and following the course of a gonococcal infection, especially arthritis, there is evidence of an increase in the bacteriolytic titer of the blood plasma. This is an immune response that can be regarded as an aid in the destruction of the organism. Patients tend to develop a higher bacteriolytic titer in their serum against their own organism than against other strains. The gonococcus complement fixation reaction is a valuable method in the diagnosis of arthritis caused by the gonococcus. The titer of complement of the blood serum is not depressed during the course of gonococcal arthritis. Agglutination tests were of no value in diagnosis, since they were invariably negative. The possible significance of bacteriolysins in gonococcal infections is discussed.

Thermal Injuries.—Harkins and Harmon consider the problem of freezing from the standpoints of the local lesion and therapeutic management of the frozen member and of the general effects of freezing, including the possible presence of secondary shock and depression of the general body temperature. Their work did not help to elucidate the local treatment of a frozen member. Although experiments indicated no difference in the response of dogs' legs and rabbits' ears to slow and rapid thawing, the experiments were not conclusive. Thus this aspect of the question is still left in abeyance, although doubt is cast on the efficacy of the time-honored custom of gradual thawing. The extreme drop in general body temperature recorded in several of the experiments may have been influenced by the barbital narcosis, but the restoration of a more normal body temperature in several instances after the removal of the ice augurs against this to some extent. It is quite possible that such low temperatures would not have been obtained if a less severe freezing agent than solid carbon dioxide had been used. However, these low readings indicate that even the

higher mammals may be relatively poikilothermic under certain conditions. Secondary shock is of interest in freezing. The lowered bleeding volume, the changes in blood concentration, including increase in hemoglobin percentage and hematocrit reading, and the marked leakage of plasma-like fluid into the tissues that have been frozen indicate that there is a similarity between the effects of freezing and burning. Both these thermal injuries produce a local reaction and resultant secondary shock. Furthermore, the secondary shock following thermal injury is similar to secondary traumatic shock following other types of injury. The similarity in the reaction of the mammalian organism to injury is most apparent when the comparison is made between the different types of thermal injury. Under natural conditions it is difficult to conceive, however, a situation in which enough of the body could be frozen to produce shock without the effect of exposure to cold being an important if not a dominating factor. In burns, on the other hand, extensive local burning without rise in general body temperature is the rule rather than the exception.

Aminoacetic Acid Synthesis in Patients with Progressive Muscular Dystrophy.—Thomsen performed experiments on six patients with typical cases of progressive muscular dystrophy. On the day of the experiment and the day preceding it the patients were served an aminoacetic acid-free diet consisting of milk, cream, butter, eggs, sugar, bread baked from potato meal and whites of egg and courses prepared from these ingredients with the addition of salt and spices. It was the author's aim to give the greatest possible amount of benzoic acid during the day of the experiment, in order to get an acceptable amount of aminoacetic acid synthesized. He found that patients with progressive muscular dystrophy can synthesize almost unlimited amounts of aminoacetic acid for use in the synthesis of hippuric acid. From this the conclusion is drawn that progressive muscular dystrophy cannot be caused by a defective synthesis of aminoacetic acid and that the beneficial effect of aminoacetic acid treatment cannot be due to aminoacetic acid acting as a supplement to the organism's own insufficient production, as held by Thomas and co-workers. The experiments showed no reduction of creatinuria when benzoate was fed, so that this observation does not support the hypothesis that creatine is synthesized from aminoacetic acid.

Immunization with Active Virus of Influenza.—Stokes and his associates describe the intramuscular vaccination with active swine and human influenza virus of a group of persons in a large state colony, in the presence of an oncoming epidemic of "influenza." They vaccinated 110 persons with human virus and 138 persons with swine virus, while 550 were not vaccinated. There was a 2.7 per cent incidence of febrile cases in the group vaccinated with human virus as compared with an incidence of approximately 12.5 per cent in the other two groups. This difference is statistically significant. In a comparison of the incidence of the afebrile, the "common cold" type of infection, no significant difference was noted in the three groups. The presence of the human influenza virus during the epidemic as a probable causative agent was determined by means of neutralization tests on the serum of a number of hospitalized children in the epidemic area who had not been vaccinated. During the height of their illness no neutralizing antibodies against the human virus were found, whereas during convalescence they appeared for the first time. Studies of the nasal and throat washings from the febrile cases were not sufficient to furnish significant data. Resistance to infection and neutralizing properties of serum may be associated but probably do not always parallel each other.

Treatment of Rheumatoid Arthritis.—Gordon isolated strains of streptococci from 100 patients with active rheumatoid arthritis. Cultures were made from roots of teeth, tonsils, throat, nasopharynx, nose, sinus puncture, urine and stool. These were grown in beef heart broth, with a p_n of from 7.7 to 7.8. Only the strains having potent soluble toxins were used. The filtrates were then treated with formaldehyde, the same as in diphtheria toxoid. Dilutions were then made of 1:10, 1:100, 1:1,000 and 1:10,000. Treatment by subcutaneous injection was begun with 0.1 cc. of the highest dilution and increased gradually, depending on the patient's reaction to the original test dose of the toxin and the patient's reaction to the therapeutic dose. Individual dosage is essential and must be worked out for each patient. A very slight local reaction at the site of injection was considered favorable and was used as a guide in raising the dosage. The intradermal tests were used as indicators of the type of streptococcus probably responsible and the one giving the strongest reaction was used in treatment, but only in single strain. Whenever possible, autogenous material was used. Otherwise treatment was given with the stock strain giving the strongest reaction. Treatment was given twice a week and continued for at least three to six months. Occasionally a patient reached 0.1 cc. of a 1:10 dilution and could take no higher dosage except at the risk of a marked local reaction lasting many days, and at times a focal or constitutional reaction. The latter reactions are to be avoided, as they tend to bring the patient into a higher allergic state and interfere with the attempted desensitization. The clinical results, subjective and objective, were not only encouraging but astounding, even though not manifest at times before some months had elapsed. There were objective signs of definitive improvement, locally and constitutionally. Treatment was given to many types of patients in various stages of the disease.

Snake Venom in Treatment of Epilepsy.—Finkelman treated eight institutional epileptic patients for nine weeks with snake venom (moccasin). Injections of a 1:3,000 venom solution were given, beginning with an initial dose of 0.2 cc. and increasing by 0.2 cc. until a dose of 1 cc. was reached. The injections were given twice a week until the maximal dose was reached, when they were administered at weekly intervals. The course of treatment lasted nine weeks. A local reaction

in the form of erythema and swelling at the site of injection and a general reaction evidenced by an eosinophilia were observed. The frequency and severity of the seizures were compared during the periods of no treatment, during phenobarbital therapy and during the administration of venom. During the administration of venom the frequency and severity of the seizures were greater than during the other periods and the patients were more irritable. There was no correlation between the seizures and the eosinophilic response. Venom therapy does not induce a refractory state to convulsive seizures in institutional epileptic patients but renders them more susceptible to seizures. This conclusion probably is applicable also to extramural epilepsy.

Journal of Nervous and Mental Disease, New York

Central Nervous System in Endocarditis.—In reviewing the cases of subacute bacterial endocarditis that were seen in the University Hospital during a period of five years, DeJong found that sixty-eight cases were observed in which the diagnosis was incontrovertible. Seventeen of the sixty-eight diagnosed cases were found to present clinical or pathologic evidence of involvement of the nervous system. The central nervous system was examined in thirteen of the twenty-three necropsies, and in all these cases there were pathologic changes in the brain and/or the meninges. In six of them there were emboli or infarcts secondary to emboli. In four there were emboli in one of the major cerebral vessels or large areas of infarction secondary to a major embolism, in one there were multiple emboli with septic infarcts becoming abscesses, and in one there were multiple anemic infarcts. All these cases also showed marked edema and congestion of the brain. There were four necropsies in which there was purulent, metastatic meningo-encephalitis, mainly on the basis of multiple small abscesses in the brain substance and meninges. In addition there were three cases that showed edema, congestion and hyperemia of the brain without more specific changes. Ten of the seventeen cases with involvement of the nervous system showed definite neurologic syndromes on clinical examination. Six were admitted to the hospital because of the complications of the nervous system, two presenting the picture of meningo-encephalitis and four exhibiting evidence of embolic phenomena. In the four other cases neurologic manifestations developed that were recognized while the patients were under observation.

Tuberculosis of the Prostate Gland.—Moore made microscopic examinations of the sections of 678 prostates. There were 163 cases of tuberculosis of one or more organs. This is the result of macroscopic examination only. In these 163 cases tuberculosis of the prostate was found in twenty (12.3 per cent). There was bilateral involvement in thirteen and

unilateral in seven. Eleven of the twenty cases were diagnosed in the gross. In the remaining nine cases the lesions were small with a minimal amount of caseation. If caseation is not present, the identification of the small yellow tubercle among the normally yellow granular glands is difficult. Typically, the lesions are located in the peripheral parts of the posterior and lateral lobes. There are focal areas with an irregular scalloped border which may become confluent. They are rubbery or crumbly in consistency and grayish yellow or yellow. As a rule there are larger lesions at the periphery, with smaller lesions converging along the lines of the ducts. Carcinoma gives irregular white or whitish yellow foci, but they do not have a scalloped border and are firmer in consistency. Inspissation of a lipid-rich secretion gives a yellow crumbly mass but is regular in outline and may be shelled out to leave a cavity, the walls of which are smooth. The seminal vesicles may or may not be involved. In this series they were involved in only 15 per cent of the cases. The ejaculatory ducts are involved with the vesicle and the sharply outlined caseous duct is very typical. The microscopic lesions readily divide themselves in two classes: caseous foci and miliary tubercles. The earliest caseous lesion that has been observed consists of a central mass of necrotic acidophilic and basophilic cellular debris in the wall of an acinus just beneath the epithelium. The miliary tubercle is similar to those in other organs. It is clearly in the stroma and not related to acini. There is usually a central giant cell with surrounding epithelioid cells and lymphocytes. It seems most probable that the bacilli in most cases reach the prostate through the blood stream and first invade the periacinous tissue and acinous lumens. There is histologic or correlative evidence that the prostatic lesion is secondary to other urogenital tuberculosis in less than 20 per cent of the cases.

Chronic Hyperthyroidism.—Young and Krantz contend that too much emphasis has been placed on the noncritical acceptance of the results of the basal metabolic rate. This has meant that certain patients have been needlessly operated on and that others, who would have been benefited greatly by operation, have not. Too careful evaluation of the history and physical examination cannot be made. The metabolism test should be used not as a basis for diagnosis but as added evidence for or against hyperthyroidism. The exclusive acceptance of hyperthyroidism, because of an elevated basal metabolic reading, may in many cases lead to an erroneous diagnosis. Full knowledge of the fact that such conditions as nephritis with hypertension, malignant conditions, asthma, polycythemia, pernicious anemia and the leukemias may and do cause an

elevation of the basal metabolism must be accepted. Such an elevation, without goiter or clinical signs of hyperthyroidism, should suggest to the clinician a repetition of the test, plus a careful clinical search for the other factors that might be responsible. Of twenty-three cases of hyperthyroidism in nodular goiter in which there was a basal rate of from -34 to $+20$, nervousness was complained by all before operation, while after operation this symptom had disappeared. In nineteen cases there was tremor prior to operation and in four this symptom remained afterward. Emotional instability was present in twenty patients and nine still complained of this to some degree. Cardiac palpitation was complained of by four individuals and this symptom disappeared entirely after operation. Tachycardia was a common complaint, being present in twenty-two cases, but only in two was this noted to any degree later. Dyspnea was present in twenty-one individuals and it still persisted in eight after operation. Strength was below par in sixteen, but it was regained in all after operation, while loss of weight was regained in the seventeen patients who had noted it. Seventeen, or 73.9 per cent, of the patients stated that they had been cured by the operation and were now in normal health. In six, or 26.1 per cent, there had been improvement, but in no case did the operation fail to produce beneficial results. The lowest basal metabolic rate before operation was -34 . After operation the rates varied from -30 to $+16$. The mean value for the rate before operation was found to be $+2$, while after operation the value had dropped to -1.6 , a lowering of 3.6 points following thyroidectomy.

Primary Malignant Growth of Small Intestine.—Rowe and Neely state that, as a rule, symptoms of malignant tumors of the small intestine are vague before the onset of complete obstruction. Early appearance of visible peristalsis in any part of the abdomen and occult blood in the stool should make one think of tumor of the small intestine. Cases are usually diagnosed by the surgeon as intussusception or obstruction of the intestine, and the true pathologic condition has been revealed either at operation, biopsy or necropsy. Intestinal obstruction, intussusception, acute abdomen and exploration of a suspected tumor mass are the common preoperative reasons given for the operation. In most cases the roentgen examination, if

employed, has consisted of preliminary roentgenography or a routine gastro-intestinal examination, not timed for the special observation of the small intestine. Certain conditions and drugs must be understood or they complicate the picture. Hyperthyroidism causes increased motility. Myxedema causes slowness and slowed evacuation. Inanition delays evacuation. Loss of consciousness stops all movements. Atropine slows all movements. Fat delays grosser movements, and achylia increases motility. The roentgen examination of the small intestine, properly carried out, consumes time and is a relatively expensive procedure. In properly selected cases it will disclose the solution to an otherwise puzzling problem. Clinicians are recognizing more and more the value of a careful examination in obscure lesions of the gastro-intestinal tract. Positive changes depend on the stage of the disease. They are not always infallible, and because of the lateness of an opportunity to study the usual case, the observations may not be very determinate. Even positive signs may not be pathognomonic, nor does a negative examination exclude the possibility of a tumor. There must be careful and intelligent correlation of the clinical observations with the objectives of the roentgen examination. Study of the small intestine should begin when the stomach first begins to empty. After the examination of the stomach, further observation of the small intestine should be made at intervals of half an hour—at six hours for ileum, at nine hours for the ileac stasis and again at twenty-four hours for occasional ileac stasis. Ileac stasis, or gas, in the small intestine always needs explanation. A barium sulfate enema should be employed not only for colon but also for a complete ileac study. Sometimes the contrast enema is an advantage.

Carbohydrate Metabolism in Osteoporosis and Paget's Disease.—Moehlig and Adler stress the close association between carbohydrate metabolism and osteoporosis and Paget's disease. Twenty-six patients with Paget's disease, from 34 to 67 years of age, were studied. Dextrose tolerance tests were made on eighteen, sixteen of whom had a diabetic type curve; two were normal. Of all patients, 61.5 per cent had diabetic dextrose tolerance curves; 88.8 per cent of the patients having the tolerance test were of the diabetic type, 30 per cent gave a familial history of diabetes, 83 per cent gave a familial his-

tory of obesity and 78 per cent gave a familial history of tallness. Adenomatous goiters were present in 44 per cent of the patients, of which 15.5 per cent were calcified; 32 per cent had thyroparathyroidectomy. Of the women patients, 33.3 per cent had fibroids of the uterus. Of this number, 75 per cent were calcified as shown by roentgenograms and at operation. In 15.6 per cent of the patients, renal calculi were demonstrable by roentgenograms, cystoscopy and operative removal, and gallstones were present in 11 per cent. In the osteoporotic group there were twenty-six patients. The ages ranged from 40 to 70 years. Twenty had dextrose tolerance tests, and eighteen of this number showed a diabetic type of curve. Two had normal curves, and in six no studies were made. A diabetic type of tolerance curve was evident in 70 per cent; that is, 90 per cent of those having the test showed a diabetic dextrose curve. In 34 per cent a familial history of diabetes was obtained, 70 per cent gave a familial history of obesity and 84 per cent gave a familial history of tallness. Of this group 65 per cent had adenomatous goiters, 24 per cent of which were calcified. Of this group 38 per cent were operated on, 27 per cent having had a thyroparathyroidectomy. Of the women patients, 47.6 per cent had fibroids of the uterus. Calcification was demonstrated by roentgenograms and operative removal in 30 per cent of this group. Renal calculus was demonstrable in 15 per cent by roentgenograms, cystoscopy and operative removal, and 16 per cent of all patients had gallstones demonstrable by roentgenograms or operative removal. Thyroparathyroidectomy or thyroidectomy had no permanent influence on the bone lesions or the bone pains in either disease, nor did these procedures eliminate the diabetic type of curve. No case of tetany developed after parathyroidectomy even after removal of two and even three parathyroids. No striking pathologic lesions of the parathyroids were found in either group. In the osteoporotic group the onset of symptoms frequently began at or near the menopause. The calcification of goiters and fibroids as well as renal calculi associated with frequent arteriosclerosis in both groups would indicate that the bone lesions surrender calcium to the soft tissues. The feeding of calcium, viosterol and vitamin D in these diseases would seem to be contraindicated, as this has a tendency to increase deposition of calcium in the soft tissues. So far the use of insulin and a measured diet has given symptomatic relief of pains, weakness and fatigue. Three patients with Paget's disease over a period of a year using insulin and a measured diet show that the bone lesions are stationary in two and progressive in one.

Reactions Following Intravenous Infusions of Acacia Dextrose.—Studdiford presents three cases with a syndrome characterized by cyanosis, dyspnea, tachycardia and pulmonary edema following the use of acacia dextrose solution intravenously. Two of these patients died, and one recovered and is still living. One patient came to necropsy and showed an extensive destructive lesion of the liver. The influence of acacia solution in this group is almost without question. Three other cases are reported. In two of these a similar syndrome appeared after the use of acacia dextrose. Both patients died. One necropsy was obtained and showed a liver lesion similar to that noted before, but much less advanced. The other patient showed extensive subcutaneous ecchymosis and edema limited mainly to the face and neck and occurring after the use of acacia dextrose infusion. She died a few weeks later. Necropsy showed "acute yellow atrophy" of the liver. The influence of acacia in the second group of cases is not quite as clear but is highly suggestive. Recent experimental work is reviewed showing that liver damage is likely to follow the intravenous use of acacia and that acacia causes serious disturbances of the red cells, interfering with normal gaseous interchange, increasing the tendency to rouleau formation and causing a rapid sedimentation rate. Conglutination of red cells may occur, producing capillary blockage.

False Roentgenograms of Cancer of Stomach.—Savignac believes that the importance of a niche in roentgenograms may be disputed, especially with regard to the diagnosis of cancer. He bases his conclusions on three observations. The first patient showed a persistent prepyloric irregularity and a depression which scarcely ever was filled by opaque substance. But this depression varied in contour. Resistance, eliciting pain, was felt on palpation. The stomach was empty after five hours. The diagnosis of cancer was changed later because of the age (27 years), the inconstancy of the niche and its localization. It proved to be an alcoholic gastritis, which yielded to treatment and temperance. The second patient was a woman, aged 63, with a clinical syndrome of ulcer dating back many years. She presented a hard mass, which was painful, irregular in outline and movable on respiration. Examination for occult hemorrhage was negative, but the roentgenograms were typical of a neoplasm. An exploratory operation was refused. But the patient improved generally, although a second roentgen examination showed aggravation of symptoms. Suddenly the patient developed symptoms of paralysis agitans and died of pneumonia. The necropsy revealed an old ulcer of the anterior aspect of the stomach, but no cancer. The third patient was a man, aged 61, a hard worker and slow eater, complaining of gastric acidity and burning, especially late after meals. The opaque meal revealed a neoplastic zone of infiltration in the prepyloric region, with no pyloric stenosis but a rather narrowed passage. An exploratory operation was rejected. A second roentgen examination showed improved symptoms with beginning pyloric stenosis. In all these cases an exploratory operation would have constituted a smaller hazard than expectant treatment.

Sternal Puncture in Leishmaniasis.—Many physicians hesitate to puncture the spleen. They therefore seek to confirm the diagnosis by utilizing the fixation reaction after Makas-Angelopoulos or by means of other easy methods mostly in use in France and in Anglo-Saxon countries. Lorando regards the direct search of leishmanias as the only reliable method which would lead to a diagnosis. Makas (1934) was the first to utilize the marrow of the tibia for the diagnosis of kala-azar in fifteen children, eleven of whom had a positive reaction. The author in his research for leishmanias made sternal punctures in six patients in 1936 and all had a positive reaction. These cases were subsequently treated with intravenous injections of ureostibamine (about seven doses of from 0.05 to 0.12 Gm.), after which a second puncture proved altogether negative.

Bony Marrow Puncture in Mediterranean Kala-Azar.—The only proof for the diagnosis of kala-azar is the demonstration of the parasite. Giraud and Gaubert had little success with blood culture. In the puncture of the spleen they obtained a more reliable method, but it subjects the patient to an often dangerous peritoneal hemorrhage. The puncture of superficial glands is not injurious, but its results are not reliable. Punc-

ture of bony marrow gives sure results and is absolutely innocuous. Local anesthesia is not necessary and is often rejected by the patients. The authors use a small trocar, which is sterilized dry to avoid subsequent diluting of the marrow. The site of the puncture is the external aspect of the upper tibial epiphysis, about 1 cm. below the knee joint. The trocar is inserted until resistance is no longer felt and the point of the needle reaches the spongiosa, from which some marrow is withdrawn. It is then put on slides. The smallest specimens are sometimes the best, as they are not diluted. It is therefore not feasible to apply suction or to wait for blood to ascend into the trocar. If no material is obtained by the puncture, the other side should be tried. The technic is easy in infants and becomes more difficult with advancing age of the child owing to increasing ossification. The authors preferred the puncture of the spleen beyond the age of 10, as the patients would never submit to a sternal puncture. Of twenty-two cases the authors obtained fifteen positive results.

Diagnosis and Treatment of Cerebral Traumas. C. Vincent.—p. 405.

Intracranial Section of Auditory Nerve.—Ombredanne utilizes Dandy's method in a modified form: partial section of the auditory nerve, which suppresses vertigo and pain but saves the sense of hearing. Of nineteen cases of simple Ménière's syndrome in which operation was performed, all were successful. Of seventeen patients with atypical Ménière's syndrome, fourteen were cured, two died and in one the symptoms persisted. Some of these patients were very vertiginous, were deaf in one ear, and had an intolerable tinnitus. The two deceased were chronic otorrheic patients who previously had several operations. The patient is prepared with sedatives a few days before the operation. He is made to lie on his abdomen and with his head beyond the border of the table on a special support. Under local anesthesia the incision starts about an inch and a half below the external occipital protuberance near the median line, runs obliquely upward toward the postero-superior angle of the mastoid, and goes straight down to the inner side of the apex of the mastoid. When the zone is exposed, care must be taken of the mastoid vein and of the suboccipital venous plexuses. The trephine opening is made with a large drill into the horizontal part of the occipital bone, about an inch from the posterior border of the mastoid and from the upper curved line of the occipital bone. The orifice is then rapidly enlarged by means of semicircular forceps, but cautiously lest the mastoid cells be opened. With the aid of a small hook the dura is drawn back as much as possible from the cerebellum and a crossed incision is made, resulting in four flaps. The postero-inferior aspect of the cerebellum is then raised. The arachnoid over the posterior cistern is incised. A retractor is then inserted between the petrous bone and the cerebellum and the latter is pushed slowly inward while the retractor is gradually forced deeper. Evacuation through suction of the pontocerebellar cistern gives access to the auditory nerve. The two branches of the auditory nerve are separated and the thicker, the vestibular, nerve is cut. Its two ends are receding immediately, leaving the cochlear nerve intact. The dura is then carefully sutured with fine catgut or silk and a drain of horse-hair is left for from twenty-four to forty-eight hours between it and the skin flap. Among the postoperative events may be mentioned a violent nystagmus, which disappears in from ten to twenty days, and vomiting and vertigo, which vanish soon. The same may be said of the occipital headache, the elevation of temperature (100.4 F.) and diplopia. But the original pain, dizziness and tinnitus, so strong at the time of the operation, do not return.

Value of Aschheim-Zondek Reaction in Diagnosis of Cerebral Tumors. M. Monnier.—p. 412.
*Demianoff's Sign in Lumbago and Funiculitis. J. Vinocour.—p. 416.

Demianoff's Sign in Lumbago and Funiculitis.—Vinocour maintains that the Lasègue sign is not sufficient for the diagnosis of sciatica. It is a mosaic of different symptoms, not one of which is characteristic of the disease of the sciatic nerve alone. Demianoff of the University of Veronesh described a modification of this sign tending to convert it into a differential diagnostic sign between lumbago and sciatica. By bending the extended limb on the coxofemoral joint the corresponding half of the body becomes lowered and with it the muscle fixed to the sacrolumbar segment. Lowering stretches and traumatizes the muscle and, in case of lumbago, brings forth a sharp pain in the lumbar region. Demianoff thinks that the sciatic nerves are not responsible for pure lumbago and that for this reason the Lasègue sign is negative. The pains are not caused by the stretching of the nerve but by the distention of the affected muscles at the posterior aspect of the pelvis. He demonstrates this by fixing with one hand the anterior upper iliac tuberosity while with the other hand he elevates the leg of the same side. In this manner the pelvis is fixed and the leg can be painlessly raised to 90 degrees, while without fixing the pelvis the leg cannot be raised above 15 or 16 degrees. In the coexistence of sciatica with lumbago, Demianoff's sign is negative on the side of the sciatica, but when the opposite leg is raised there is pain before fixation and none during fixation. In double sciatica with lumbago, Demianoff's sign is again negative. Thus, in contrast with Lasègue's sign, Demianoff's sign has muscular but not nervous characteristics. However, muscular pain is not always allied with muscular rigidity. Lesions of the sciatic nerve elicit trophic alterations and accumulation of toxic products in the muscle. This is why often only a lessening of pain and not its complete disappearance is noticed in Demianoff's procedure. In a case seen by Sicard and Forestier there was a reactive inflammation of the extrameningeal part of the roots from pressure. The patient recovered after a double laminectomy of the third to fifth lumbar vertebrae. Demianoff's sign may be used as a symptom in local lesions of muscles, upper lumbar nervous roots and funicular sciatica.

Policlinico, Rome

44: 121-172 (March 15) 1937. Surgical Section

- Traumatic Nephritis: Experiments. D. Ciddio.—p. 121.
Syringomyelic Arthropathy: Case. E. Leni.—p. 134.
*Echinococcosis of Kidney. G. Millul.—p. 154.
Spontaneous Perirenal Cystic Hematoma: Case. L. Ugelli.—p. 162.

Echinococcus Cyst of the Kidney.—According to Millul, the history of the patients suffering from echinococcus cyst of the kidney and their objective and urologic examinations show the presence but not the nature of renal disturbances. Roentgen examination of the urinary tract shows the presence of renal tumor. The differential diagnosis of renal tumor and echinococcus cyst of the kidney is made from the special modification of the renal pelvis and of the calices, as shown by ascending pyelography, which is different in each condition. Entrance of the opaque substance in the cyst indicates a communication between the cyst and the renal pelvis and excludes the diagnosis of polycystic kidney. The pyelographic diagnosis is confirmed by the results of certain biologic tests. Urticaria is a sign of diagnostic value, provided the presence of idiopathic urticaria is excluded. It is due to entrance of hydatid fluid in the blood from rupture of the cyst, or to an anaphylactic reaction of the body to hydatid products. The reaction does not take place in other pathologic conditions of the kidney. Patients suffering from echinococcus cysts of the kidney have intense eosinophilia, which is not of diagnostic value because it occurs frequently in other parasitic infestations and nonparasitic pathologic conditions. Casoni's intradermal reaction of local allergy and Ghedini-Weimberg's reaction of the complement fixation are biologic tests of diagnostic value and are specific. Casoni's

reaction is specific in 92 per cent of the cases. The treatment of choice is nephrectomy, but if the latter is contraindicated a conservative treatment is resorted to. One case is reported.

Rinascenza Medica, Naples

14: 115-144 (Feb. 28) 1937

- *Diagnosis of Latent Chronic Pancreatitis. J. W. Grott.—p. 115.
Echinococcus Cyst of Scarpa's Triangle: Case. F. Rabboni.—p. 119.
Tuberculous Anemia and Liver Therapy. G. Mesirca.—p. 120.

Diagnosis of Pancreatitis.—Grott's method for diagnosis of latent chronic pancreatitis consists in the determination of the presence or coexistence of one or several of the following conditions: glycosuria, increase of the amount of pancreatic diastase in the urine and pain at the pancreas. The history in these cases shows involvement of the pancreas in previous pathologic conditions of parapancreatic organs. The presence of pancreatic pain is determined by palpation. Glycosuria is determined two hours after administration of a solution of 50 Gm. of dextrose. The increase of pancreatic diastase in the urine is determined after administration of a test meal. In determining the pancreatic diastase, freshly eliminated urine is used because the amount of diastase diminishes by exposure. Out of a group of 141 patients, a diagnosis of latent chronic pancreatitis was made in fifty-three cases from the presence of glycosuria and in eighty-eight cases from that of a painful pancreas. The test of produced glycemia gave negative results in forty-one cases in this group. The remaining forty-seven were diabetic patients. Glycosuria was not taken into consideration for the diagnosis of the coexistent pancreatitis in these cases. The amount of pancreatic diastase in the urine was increased in forty-four cases of the group. The negative results of the tests do not necessarily exclude the presence of latent chronic pancreatitis, but the number of cases in which a diagnosis can be made by the author's method is large.

Rivista di Patologia e Clin. d. Tuberculosis, Bologna

11: 162-236 (March 31) 1937

- Physiopathology of Fattening in Tuberculosis. E. Leni.—p. 161.
*Influence of Exeresis of Phrenic Nerve in Pulmonary Tuberculosis on Contralateral Lung. V. Maccone.—p. 186.
Weltmann Serocoagulation Test, Velocity of Sedimentation and Blood Changes in Extrapulmonary Tuberculosis in Patients at Near-Sea Sojourn. M. Candida.—p. 207.

Influence of Phrenic Exeresis on Contralateral Lung.—Maccone studied the results of 153 phrenico-exereses in patients suffering from unilateral or bilateral pulmonary tuberculosis. The most frequent functional modifications of the contralateral lung and hemithorax are those of the respiratory excursions of the hemidiaphragm and of the costal wall and also those of the intrapleural pressure, as well as displacement of the mediastinum. The variations do not necessarily follow phrenico-exeresis in all cases. When they take place they are unrelated to the subsequent bilateralization of tuberculosis to a normal lung and to the evolution of previously existing tuberculosis. The favorable or unfavorable evolution of preexisting tuberculosis following phrenico-exeresis in bilateral tuberculosis parallels that of tuberculosis of the lung of the side on which the operation is made. The results on both lungs are evident shortly after the operation. Bilateralization sets in after failure of phrenico-exeresis to control acute or subacute tuberculosis of the lung on the side on which the operation is done. An influence, favorable or unfavorable, of phrenico-exeresis on the contralateral lung is more frequently induced in exudative than in productive tuberculosis. The etiopathogenesis of the functional and anatomic changes induced by phrenico-exeresis is complicated. It is related to the reaction of several organic factors or to certain local or mechanical conditions created by the operation. The factors involved are (1) a general organic and local tissural reactivity to tubercle bacilli and, in this connection, action of phrenico-exeresis on immunity and local organic defenses in the given case, (2) clinical and anatomic nature of the tuberculous lesions and reaction of the lesions, (3) intensity of tuberculous and nontuberculous toxemia and its modifications, and (4) collapse or hyperdistention of the contralateral lung with consequent respiratory alterations. According to the author, phrenico-exeresis has neither a favorable nor an unfavorable direct action on the contralateral lung. Its action is indirect through modifications of several pathogenic correlated factors.

Revista de Cirugía, Buenos Aires

15: 625-692 (Dec.) 1936

- Paraperitoneal Anterior Lumbar Sympathectomy. A. Gutierrez.—p. 625.
 *Diverticula of Bladder. M. A. Llanos.—p. 635.
 Postoperative Peptic Ulcer. B. Labandibar.—p. 646.

Diverticula of Bladder.—Llanos discusses the subject of congenital diverticula of the bladder, especially from the point of view of treatment. He states that abstention treatment is indicated only in latent small or large uncomplicated diverticula, especially in the elderly. Otherwise the treatment is surgical. The operation varies with the given condition. Removal of the diverticulum through an ample suprapubic incision, followed by introduction of a sound in the bladder and of an extra-vesical drain and final suture of the incision, is indicated in uncomplicated diverticula of the bladder causing retention of urine or hematuria. In cases complicated by infection, the bladder and the diverticulum are opened and drained. Once the infection is controlled, the diverticulum is removed and the bladder treated as after removal of uncomplicated diverticula. In the presence of hypertrophy of the prostate or of the vesical neck, a cystotomy is done, the infection is controlled, the hypertrophic tissues are removed and the diverticulum is enlarged and drained. In cases of complicating lithiasis the calculi are removed through a cystotomy and the bladder and diverticulum drained. Both in hypertrophic and in lithiasic complications the diverticulum is removed at a second operation if symptoms persist after the first operation. In cases of complicating malignant tumors the operation will include removal of the diverticulum with all the involved organs, even the ureter and the kidney, if it is necessary. In cases of benignant tumors the tumor may be treated by electrocoagulation or removed and the diverticulum removed if it is necessary. In cases of diverticula associated with benignant tumors and causing retention of urine or hematuria, removal of both the diverticulum and the tumor is indicated. The author has no favorable opinion on the technic of inversion of the diverticulum into the bladder or on Geraghty's technic with resection of the diverticular mucosa. He reports three cases in which an operation was done with satisfactory results.

Fortschritte a. d. Gebiete der Röntgenstrahlen, Leipzig

55: 211-318 (March) 1937. Partial Index

- Functional Examination of Diseased Colon. F. Berner.—p. 211.
 *Anatomic and Roentgenologic Aspects of Pneumatosis Cystoides Intestinalis. H. Urban.—p. 231.
 Pericardial Calcifications. O. Rummert.—p. 241.

 An Especially Extensive Form of Honeycomb Lung. F. A. Nolte.—p. 273.
 Etiology and Diagnosis of Perinephric Abscess. V. Hormuth.—p. 277.

Pneumatosis Cystoides Intestinalis.—Urban states that pneumatosis cystoides intestinalis, in which gas cysts form in the intestinal wall, has never been diagnosed in the living patient except in the course of operative interventions. By the comparison of surgical and necropsy observations with clinical and roentgenologic aspects, it has been demonstrated that the appearance in the roentgenogram of certain areas of lesser density in the intestinal wall and interpositions of intestinal loops between the liver and the diaphragm may be of help in the diagnosis. Pneumatosis cystoides intestinalis is a rare disorder, for the world literature reports only about 140 cases. The case reported here is noteworthy because the diagnosis could be based only on the presence of pneumatotic changes in the abdominal lymph nodes, which were detected during the necropsy. The postmortem examination did not show macroscopic pneumatotic changes in the intestine; only the microscopic examination revealed remnants of changes of a pneumatotic character in the wall of the colon. This case had been under observation for several years, but in spite of careful clinical examinations it was not correctly diagnosed during the life of the patient. After the diagnosis of pneumatosis had been reached on the basis of the necropsically detected changes in the lymph nodes, the inspection of a roentgenogram that had been made in the course of the clinical observation disclosed changes in the intestinal wall indicative of the fact that at the time a pneumatosis of the large intestine existed. In roentgenograms taken four weeks after this one the pneumatotic

intestinal changes had largely disappeared. This corroborates the observation reported in the literature that the pneumatosis, which may produce ileus-like symptoms, may disappear within a comparatively short time.

Vasography as Functional Test of Peripheral Vessels.

—After reviewing previous vasographic studies and evaluating the various contrast mediums, Ratschow gives his attention to the demonstration of veins and varices, showing that the circulatory conditions can be vasographically demonstrated in every varicose region but that these tests must be made while the patient is standing. The time that elapses from the time of injection of the contrast medium to the total evacuation of the contrast blood into the deep veins gives information about the functional condition of the varicose system, and the author shows how the information thus obtained is helpful in the obliteration treatment of varicose veins. Further, he reviews studies on the lymph vessels and then gives his attention to the arterial system. He shows that, by combining the intra-arterial injection with stimuli that influence the width of the vessels, it proved possible to produce arteriograms that indicated the functional capacity of the vessels. He thinks that arteriography is permissible in those cases in which later amputation has to be considered. However, owing to the danger of possible mishaps, he does not consider it advisable for general diagnostic application.

Weltmann's Coagulation Band and Takata Reaction.

—After briefly stating the nature of Weltmann's coagulation band and of Takata's flocculation reaction, Rosegger reviews the literature on both tests and points out that both give information about the condition of the serum, but from different aspects. Whereas the coagulation band reveals the fibrous or exudative character of the existing disorder, the Takata reaction discloses the albumin-globulin relationship. The author further cites observations from the literature which indicate that both reactions are especially valuable in diseases of the liver and then discusses his own observations with the two tests in 168 cases. He found that in diseases of the liver the impairment of the hepatic cells is indicated by a widening of the coagulation band and that the Takata reaction reveals the degree of the impairment and the prognosis. In some cases with an abnormally wide coagulation band, the outcome of the Takata reaction indicates whether the disorder is in the liver or not. In a number of other disorders, the information obtained from the coagulation band is complemented, particularly as regards the prognosis, by the outcome of the Takata reaction. An involvement of the liver, the kidney and the bone marrow should always be taken into consideration in these cases. A narrow coagulation band usually excludes a positive Takata reaction, but nephritis may be an exception to this rule.

Benzene Poisoning in Rubber Gluers.—Holstein reports that a considerable number of workers, who were occupied in gluing together rubber materials with a solution consisting of india rubber (7 per cent) and benzene (93 per cent), complained of fatigue, exhaustion, headaches, dizziness and pains in the joints. In the evening they often felt as if intoxicated. Other complaints were fainting, loss of appetite, nausea, stomach ache, loss of weight, pallor, nasal and gingival hemorrhages and increased menstruation. There also were cases of anemia and hemorrhage, which might have been due to the action of benzene. After giving brief histories of some of the patients, the author mentions the measures that were taken to avoid further cases of poisoning. The ventilation of the shop was improved and the benzene solution of india rubber was replaced by a much less harmful benzine solution of india rubber.

FATAL "ASTHMA"

A CLINICAL AND PATHOLOGIC CONSIDERATION
OF 187 CASES

R. W. LAMSON, PH.D., M.D.

AND
E. M. BUTT, M.D.
LOS ANGELES

The original meaning of "asthma" was "panting," and today the term is being loosely applied to a variety of conditions: the so-called thymic, renal, cardiac, bronchial or other type of asthma. These may bear a slight resemblance to one another in some of their manifestations, yet they are very dissimilar in their etiology, mechanism and clinical course. Consequently, the term asthma has no universally recognized meaning or application.¹ Rackemann² advises one to regard the word as denoting a symptom and to think of it as in the same category with "headache" or "nausea" or even "angina." In the textbook by Norris and Landis,³ one finds this comment: "By the term 'bronchial asthma' is meant a form of paroxysmal dyspnea, the characteristic feature of which is a marked diminution or arrest of the respiratory movement with prolonged expiration: a condition sometimes referred to as spasmodic asthma."

The hazards of "asthma" is a subject recently investigated by certain life insurance organizations. It may not be amiss to examine their conclusions. In 1932 Old⁴ reported before the Society for the Study of Asthma and Allied Conditions an investigation carried out by the Association of Life Insurance Medical Directors. This seemed to indicate that the ratio of the actual to the expected deaths in asthmatic patients was, in 274 cases, 121 per cent plus or minus 5 per cent. In that group of individuals in whom the condition was found on examination, or the insured had had one or more attacks within five years, the death rate from organic disease of the heart was three and one-fourth times the normal. He believes that the two main causes of death in these individuals are diseases of the lungs or diseases of the heart. Dublin and Marks⁵ found in a similar series that twenty-five of the deaths in a group of ninety-nine males were from heart disease and all but three of these from organic heart disease. In males the

heart disease mortality is about two and one-third times the normal. They conclude in part as follows: "On male risks with asthma the mortality in the aggregate is 27.4 per cent in excess of the expected by the American Men Table, and 63.7 per cent by the Basic Mortality Table. The results on female risks are even worse. These mortality results, as well as the findings of earlier insurance studies on asthma, are in sharp contrast with the observations of many clinicians, with extensive experience in treating the condition, that the prognosis in asthma is excellent. As Bray strikingly puts it, 'Many asthmatics pant on to a good old age.' " These statements are indeed so much at variance with clinical experience that they are in effect a challenge.

It seemed logical to consult first the available literature on the subject of fatal asthma: the writers just mentioned seem to have ignored this point. We were early impressed by the paucity of case reports, particularly those including necropsies. The first one was by Van Leyden¹ in 1886 and the most recent one by Michael and Rowe.⁶ Coca¹ has summarized the first thirty-three cases in chronological order but omitted one case reported by Rackemann⁷ which we have included. In the discussion of these he admits that some of this group are examples of "asthma" only within the broadest use of this term. Macdonald⁸ added eight, and several other workers have published single case histories that deserve consideration. Michael and Rowe do not attempt to analyze the previous records, but they refer to the same authors and reports that we have mentioned. They add two very complete case reports. Including these, one finds a total of fifty patients, twenty-seven males and twenty-three females, represented—an average of approximately one a year since 1886. Each patient has had a postmortem examination and in most instances the report includes microscopic observations. In a few the latter are not necessary to complete the diagnosis. In order to make certain of these data available at a glance, we have arranged the males in one series and the females in another and have plotted the age at death in ascending order of magnitude from left to right. One factor that directly relates to the controversial issue raised by Old⁴ and by Dublin⁵ is the duration of symptoms. This has been plotted on the same chart whenever the data could be determined from the report.

The average age at death of the males is 48.3 years, although fourteen patients, or 51.8 per cent, exceed this mean, and the maximum is 75 years. In the group of females the average age at death, 43 years, is less than that for the males and tends to support one of Dublin's statements. Here twelve patients, or 52.2 per cent, exceed the mean age, and one lived sixty-seven years,

eight years less than the oldest male. Two reports concern children; one is a female and the sex of the other is not given. These are charted separately and are not included in the statistical analysis but will be mentioned in later discussions.

A detailed study of the duration of symptoms will be presented in subsequent charts and tables. We wish

Fig. 5.—Frequency histogram by decades on the basis of age at death of fifty patients (previously reported).

to call attention to the wide variation, irrespective of age at death, in the period between the first and the last attack of "asthma." A long duration is not inconsistent with almost the maximum period of life. These two groups do not substantiate the statements made by life

insurance executives, and this discrepancy led us to search for further evidence before finally accepting either theory.

We are able to present information relative to 137 additional patients who have died with or because of "asthma." This group is composed of two subdivisions: (a) forty-eight patients (thirty-one males and seventeen females) examined, often inadequately, post mortem, and (b) eighty-nine individuals (sixty-eight males and twenty-one females) not so examined. Most of the authors who reviewed certain of the previously reported cases have limited their analysis to those with necropsy. We have adequate reasons for not so limiting our series, even though the "final" evidence is lacking in about 65 per cent. The most significant reasons are that approximately 33 per cent of the entire group carried life insurance and that the two reports in controversy undoubtedly included patients not examined post mortem.

The majority of the patients in our series died during the past eight years in the Los Angeles County Hospital. In the statistical files of that institution they are indexed under the diagnosis "bronchial asthma." In fact, that condition is given as the principal cause of death in a majority and as a contributory cause in most of the remainder. Many of the patients have been under the personal observation of one of us (L.) in the Allergy Clinic at that hospital, who carefully abstracted each history and attempted to reproduce the data without bias.

Although not especially significant to the present study, it is of interest to find so large a proportion of supposed indigent patients carrying a life insurance policy. In approximately twelve instances the principal sum could be determined, and it was found to average in excess of \$950. Twelve or thirteen patients were insured only in the Metropolitan Life Insurance Company, several carried a policy in it and also one in the Prudential, eight or nine in the latter alone, and the remaining patients were insured in various companies: many of these are also prominent "old line" eastern companies, and it is probable that not a few of these patients were included in the series studied by Old, by Dublin and Marks or by other insurance agencies.

In order that our unpublished data may be compared with those in the previous charts, we have presented them in identical form. The groups *a* and *b* are kept

separate, as are the two sexes. The patients without necropsies will be considered first. A comparison of figure 2 for males with those previously published, figure 1, shows marked agreement between the two. The average age at death is 56.9 years, and the minimum age is considerably higher than in the published series. Only 47 per cent of the patients exceed this mean age. The data relative to the three male infants in this chart will be considered later. The chart of female patients (fig. 3) compares similarly with the one of previously reported cases. Our females also show a greater average age at death (49.7 years) than either the male or the female group of published cases. Approximately 50 per cent of these exceed the mean age.

The final subdivision of our data (fig. 4) concerns the male and female patients who have had partial or complete postmortem examination. The males averaged 52.1 years at death, and 45 per cent exceeded this age. The average age of females was 49.4 years, and 47 per cent exceeded that age. These data are of greater magnitude than those relating to similar features in the published series. In all instances it is conspicuous that the females had a lower average age at death than did the corresponding group of males. This undoubtedly represents a real trend rather than the result of chance sampling. The general similarity of figures 2, 3 and 4 to those representing the world's literature on fatal "asthma" cannot be denied. The lack of relationship between the age at death and the age at onset, or the duration, of "asthma" is evident in each of the six groups. Since "asthma" is alleged to be a marked handicap to longevity, this feature will receive especial attention.

Possibly the age at death will be better visualized by making a frequency histogram of the fifty observations already published (fig. 5) and a similar one for our total series of 137 units (fig. 6). At the top of the bar is indicated the percentage of total patients each decade contains. Except for some askewness, the graph suggests the normal or probability curve. This is even

Fig. 6.—Frequency histogram by decades on the basis of age at death of 137 patients.

more notable in our series. The similarity, or even identity, of the percentage factor in several corresponding decades of the two series is the more striking since it was not anticipated. The agreement between these and other charts in the two series must be accepted as proof of the similarity of these groups.

The duration of symptoms, briefly referred to in preceding paragraphs, should not be dismissed without a more critical analysis. We believe it may be an

important factor in differential diagnosis and in determining the roentgenologic and possibly even the pathologic aspects. At least two important variables make this factor difficult to determine. One is the time elapsing between the first and the last attack of dyspnea, and the other the days, months or years during which the patient actually experienced symptoms. A patient may have an attack of asthma at an early age and then experience a complete remission for forty or more years. Symptoms may again appear a few weeks or months before death. The duration of the asthmatic state is, for example, forty years, but the actual symptoms have been present at the most but a few months. We have consistently employed the total period since the first attack to represent the duration of symptoms. No doubt the first attack has been forgotten or went unrecognized by some who appear to have had a very short duration. Such inconsistencies are inevitable in any statistical study. The duration of symptoms, irrespective of age, is the basis for sorting the patients in table 1.

By presenting these data for the two series in parallel columns, the comparison becomes more striking. A few points deserve especial emphasis: 17 per cent of our series, and 12 per cent of the published one, experienced symptoms for no more than one year. At the other extreme, practically the same proportion of each group, 20 per cent and 9.8 per cent respectively, survived twenty or more years. It was most unexpected to learn that 38 per cent and 44 per cent of each group had symptoms during so short a period as four years or less. One might ask what the relationship is between the age of the patient and the "short duration" and whether it appears only in the elderly individuals. The latter question can be answered in the negative as indicated when discussing figures 1 to 4. We compiled and compared in great detail the data for each of the 187 patients, even to determining the percentage of life represented by the duration of "asthma." These tables are too voluminous to publish, but they form the basis for table 1 and for many of the opinions expressed.

In general, it appears that certain of the patients may indeed have asthma much of their life and even "pant on to a good old age." However, "asthma" may lead to a fatal result in a few days or weeks even in the young adult. Our series, although nearly three times as large as the one previously published, does not even change the trends brought out in the latter group; in fact, it actually duplicates many of them. While there are some features that seem to be in accord with insurance statistics, we cannot accept the latter for reasons which we hope to bring out in the following paragraphs.

Early in the report we mentioned some inconsistencies in the use of the term "asthma" as a diagnosis. When used to designate typical cardiac dyspnea it ranks with edema or other signs or symptoms of a circulatory dysfunction. A study of some of these patients indicated that the dysfunction may be atypical and yet be a cause of the asthma syndrome. The literature affords adequate support for this statement and contains interesting explanations of these phenomena. Pratt⁹ has emphasized the similarity of some attacks of cardiac and bronchial asthma, "even to the expiratory type of dyspnea and are as a matter of fact often mistaken for the latter by physician as well as layman." Osler¹⁰ and McCrea, in their discussion of cardiac asthma,

offer an explanation of the mechanism: "The patients are usually over 50 years of age, and arteriosclerosis, myocardial disease, nephritis, hypertension, and coronary artery disease, some or all are present. A sudden rise in blood pressure, an aortic reflex, increased respiration and diminished blood supply to the myocardium during sleep are suggestions as to the cause." Pratt quotes Mackenzie, and seems to agree with him, that a reflex disturbance produced in some way by the weakened heart may result in an actual bronchial spasm. Many authors comment that the patients live on the average two or three years after the onset of cardiac dyspnea. This condition therefore may account for the high percentage of patients in the two series who lived but a few days or weeks, or a maximum of four years after the first attack. A reflex from the aorta in the region of the heart is commonly cited as the cause of paroxysmal dyspnea in cases of hypertension and syphilitic aortitis.

Chronic pulmonary fibrosis is a well known cause of at least one type of paroxysmal dyspnea; namely,

TABLE 1.—Frequency of Duration of Paroxysmal Dyspnea in Fatal "Asthma" in 187 Cases

Duration of Paroxysmal Dyspnea	Unpublished			Previously Published

"miners' asthma." The fibrotic changes produced by pulmonary tuberculosis seem to be another. Repeated attacks of bronchopneumonia or chronic bronchitis likewise lead to fibrosis, and asthma may occur on this basis. Cecil¹¹ recognized the chronic nature of interstitial pneumonia (from fifteen to twenty years) and one of the important causes of that condition: "The interstitial pneumonia of influenza seems to have led to much diffuse pulmonary fibrosis." We have several examples of this in our series, and one report indicating the problem of differential diagnosis will be given in some detail.

Chest deformities may not infrequently be the cause of attacks of paroxysmal dyspnea, and the rôle of such deformities in the production of circulatory disorders has been emphasized in the Cabot case history.¹² Space does not permit us to indicate all the literature relative to these less commonly accepted causes of paroxysmal dyspnea; we feel that our data also find support in the unquoted references.

Earlier reviewers of the literature on fatal asthma have agreed that many of the reports did not apply to true bronchial asthma. In fact, one of the recent authors felt that the latter group did not then exceed

sixteen. There has been little accord as to which patient one should consider typical or atypical. Of course, one point at issue is whether the asthma caused the patient's death. We shall place less emphasis on this and more on an attempt to determine the type of "asthma."

Ten¹³ illustrative histories were selected from the group with necropsies.¹⁴ In order to conserve space, only significant positive or negative observations are recorded. Nine of these reports are supplemented by appropriate photomicrographs. In several instances the clinical and the pathologic manifestations seem not to be in accord. When these inconsistencies are pronounced, the last paragraph of the abstract attempts to weigh the two points of view. Each patient is designated by the same identifying number employed in the respective chart.

REPORT OF CASES

CASE 11¹⁵ (fig. 4).—*History*.—A white man, aged 46, had complained of attacks of wheezing and dyspnea at frequent intervals during the previous thirty-two years. The condition was always worse at night and during extremes of heat or cold.

TABLE 2.—The Probable Cause of Dyspnea in Forty-One Patients (with Necropsies)

Cause of Dyspnea	Males		Females	
	Total Patients	Per Cent	Total Patients	Per Cent
Arteriosclerotic and hypertensive heart disease	6	12.2	5	35.68
"	2	7.4	0	0
"	1	3.7	0	0
"	2	7.4	4	28.56
"	3	11.1	1	7.14
Pneumoconiosis	4	14.8	0	0
Pulmonary tuberculosis	1	3.7	1	7.14
Tracheal obstruction	1	3.7	0	0
Asthma not excluded	7	25.9	3	21.4
Total	27		14	
Data incomplete (not included in percentage)	4		3	

Contact with horses seemed to have precipitated the first attack; subsequent skin tests revealed a marked sensitivity to this and other epidermals, to foods and to many pollens. Residence in various sections of the country afforded no relief, but he was symptom free when on the ocean. There was a short period of relief after an abdominal operation.

The general health had always been good. He had played football in college, often at the cost of several days of severe dyspnea; he had always indulged in strenuous exercise.

The patient's son and father had asthma. On numerous occasions examination had revealed excellent musculature and no significant pathologic condition except chronic emphysema, wheezing and prolonged expiration.

The terminal symptoms were severe dyspnea and wheezing of several days' duration, which failed to respond to epinephrine, a drug previously very effective in small doses. He would not remain in bed in spite of the fact that mild exertion aggravated the dyspnea. There was mild cyanosis, which rapidly increased toward the end. Medication afforded no relief; the respiratory excursions became less and less but did not entirely cease until the heart action stopped.

Pathologic Examination.—No thymic tissue was observed. The lungs were markedly emphysematous and failed to collapse on removal from the pleural cavities. The bronchial walls appeared somewhat thickened and the lumens throughout were

plugged with thick tenacious mucus. The lungs together weighed approximately 700 Gm. The heart weighed 300 Gm. The right ventricle was moderately hypertrophied and measured from 3 to 4 mm. in thickness. The valves and coronaries were normal. Sections of the bronchus are shown in figures 7 and 8. The anatomic diagnoses were (1) bronchial asthma and (2) hypoplasia of the circulatory system.

Clinically, this patient presented the classic personal and family history of an allergic asthma; the evidence of specific sensitivities substantiated this diagnosis.

For the sake of brevity we have not presented a complete pathologic description. The observations, however, agree with the more recent criteria of asthma, except for the absence of thymic tissue and of abnormal hyperplasia of lymphoid structures.

It should be noted that the pathologic appearance is not markedly different from that in several cases herein described in which the clinical observations are not pathognomonic of allergic asthma.

CASE 13 (fig. 4).—*History*.—A white man, aged 49, complained of recurrent attacks of moderately severe paroxysmal dyspnea and wheezing of seven and one-third years' duration. He was under observation at the hospital on several occasions during the past five years because of recurrent attacks of bronchopneumonia. He placed little emphasis on dyspnea and wheezing but more on a dry cough.

The physical signs on each admission were those of acute pulmonary infection; wheezing râles also were heard. Several x-ray examinations in the five year period revealed extensive pulmonary fibrosis. He had a residual paralysis of the right arm and leg and impairment of speech due to a blow on the head seventeen years previously. Most diagnoses that had been made were "chronic bronchitis," "pulmonary fibrosis" and "possible bronchiectasis." One or two physicians thought bronchial asthma was primary.

Relief was obtained with the usual doses of ephedrine and epinephrine.

The patient died in an attack of dyspnea.

Pathologic Examination.—The right pleural cavity was completely obliterated by dense adhesions. The left lung weighed 400 Gm., the right 455 Gm. and both were markedly emphysematous and contained large bullae. The bronchi were prominent and in places the walls were thickened.

The heart weighed 250 Gm. There was a slight hypertrophy of the right ventricular wall. In the anterior and inferior portion of the septum there was an area of fibrosis with a diameter of about 3 cm., which was the site of an old infarction. The coronaries were very tortuous and calcified. The lumens were reduced to pinpoint openings by closely placed atherosclerotic plaques.

Microscopic examination revealed numerous villus-like projections of the wall of the bronchus into the lumen that in places were partly covered by thickened stratified squamous epithelium (fig. 9). The lumen was filled with desquamated epithelial cells, mucus and leukocytes of various types. The muscle was only moderately hypertrophied. There was much cellular fibrous tissue about this bronchus, which extended out into the lung tissue. The wall throughout was heavily infiltrated with round cells, polymorphonuclear leukocytes and very few eosinophils.

In the 10 mm. bronchus, the wall was definitely thickened, and in places there were circular and radiating scars. There was a moderate smooth muscle hypertrophy and a thin hyalinized basement membrane. The epithelium was thrown into coarse villus-like folds, which in many instances had become detached from the wall. The wall was infiltrated throughout with round cells, plasma cells, a few polymorphonuclear leukocytes and eosinophils.

The anatomic diagnoses were: (1) local arteriosclerosis, coronaries, with scars in the heart muscle and an old healed infarction of heart, (2) chronic bronchitis, (3) emphysema and (4) chronic, adhesive pleurisy.

CASE 28 (fig. 4).—*History*.—A white man, aged 65, complained of dyspnea, wheezing and choking, of nine years' duration. The condition was always worse in cold, damp weather.

13. Six of this number are presented only in the authors' reprints.
14. It is impossible to designate herein each individual whose work has been invaluable to us. Particular mention should be made of Dr. Newton Evans, chief of the pathologic laboratory, Los Angeles General Hospital, Dr. E. M. Hall, professor of pathology, Medical School of the University of Southern California, and Dr. Ian Macdonald, whose report on the examination of the tissue from several patients we have freely incorporated in our description.
15. Dr. Robert Cocke, New York, gave us some of the data regarding this patient.

The past history revealed "dropsy" associated with "rheumatism" forty-eight years before and "dropsy" again eighteen years later. Until the past fifteen years he had been a "heavy drinker." He worked in a borax mine for several years immediately before the onset of dyspnea. He rarely had orthopnea and used but one pillow.

The patient was poorly nourished, tall and slender and had marked emphysema and prolonged expiration; toward the end some moist râles were noted along with the "music box" sounds usually present. Rough apical and aortic systolic sounds were noted repeatedly during a four year period. The blood pressure was 150 systolic, 80 diastolic. The electrocardiogram revealed sinus tachycardia. Allergic tests were negative. The condition improved for a time under vaccine therapy.

Relief was obtained with 0.15 cc. ($2\frac{1}{2}$ minims) of epinephrine (1:1,000) and three-eighths grain (24 mg.) of ephedrine, but the latter caused marked urinary symptoms.

Pathologic Examination.—The lungs were large and emphysematous. The right lung weighed 900 Gm. and contained much scar tissue. The posterior portion of the lower lobe contained areas of pneumonic consolidation. The remainder of the lung was congested. The left lung weighed 950 Gm. and was similar to the right. The walls of the large bronchi were thickened and stenosed. Beyond these stenoses they were not definitely ectatic. Everywhere there was evidence of chronic inflammation and increased fibrous tissue in their walls.

The heart weighed 425 Gm. The chambers were dilated and the right ventricle was hypertrophied. It averaged from 3 to 11 mm. in thickness. There was moderate sclerosis of the coronary arteries.

A section of the bronchus is shown in figure 13.

The anatomic diagnoses were (1) pneumoconiosis, (2) chronic bronchitis with bronchial stenosis, (3) right cardiac hypertrophy with mild congestive failure and (4) terminal bronchopneumonia.

CASE 17 (fig. 4).—*History.*—A white woman, aged 72, complained of shortness of breath and edema of the legs, face, eyelids and abdomen for the last eight weeks. She had had a chronic cough for years.

The patient had an attack of paroxysmal dyspnea eighteen years before; except for the recurrent cough she had had no other symptoms and had always been very active until eight weeks before admission. Since duration indicates the period between the first attack and death, we have used the maximum—eighteen years—in the charts.

Examination revealed obesity, marked generalized anasarca, dyspnea and prolonged expiration. There were sibilant and sonorous, also crepitant, râles throughout the chest. Wheezing was audible to the unaided ear. The heart showed the aortic second sound greater than the pulmonic second sound. The blood pressure was 140 systolic, 90 diastolic. The referring physician stated that the systolic pressure usually averaged 190 mm. of mercury. An electrocardiogram showed evidence of myocardial damage.

Death was apparently due to circulatory failure.

Pathologic Examination.—The pleural cavities were obliterated by dense fibrous adhesions. The right lung weighed 640 Gm., the left lung 600 Gm. Except for edema and minimal apical tuberculosis on the left, and emphysema, the lungs were normal.

The heart weighed 400 Gm. Its form was somewhat eccentric, owing to dilatation of the right auricle and ventricle. The wall was hypertrophied and averaged from 6 to 12 mm. in thickness. The left ventricle averaged 16 mm. One auricular appendage contained an antemortem thrombus.

Microscopic examination of a 3 mm. bronchus with cartilage showed the lining epithelium thickened and of transitional type. A moderately thick hyaline basement membrane was present. Glands were rather numerous and there was dilatation of their openings. The wall of an arteriole in the section was greatly thickened. The muscle showed only a moderate hypertrophy. The lumen was empty. The microscopic appearance of a 7 mm. bronchus is illustrated in figure 18.

The anatomic diagnoses were (1) hypertensive heart disease with congestive heart failure, (2) emphysema and (3) bronchial asthma (?).

If the history and physical manifestations can be depended on, the asthma is but a symptom of the cir-

culatory dysfunction. Microscopic examination, however, reveals some of the appearances described by others as pathognomonic of bronchial asthma.

COMMENT

Cases 11, 13, 15, 26, 28, 7, 8, 10, 15 and 17 represent approximately 21 per cent of our series with necropsies (forty-eight patients). In many of the latter there seemed to be no allergic basis for the asthma; in others it was undeniable and in a few atypical histories it could not be excluded. If an extreme degree of pneumoconiosis was present a long time before the onset of dyspnea, we feel justified in accepting it as the primary cause of symptoms. If there was an adequate basis for "cardiac asthma," this patient may likewise be excluded from the allergic group. Using such criteria,

Fig. 7 (case 11, male, fig. 4).—Section of 1 mm. bronchus $\times 80$. The lumen is completely filled with mucinous exudate. There is much infolding of the wall, and the epithelium rests on a thick hyaline basement membrane. The muscle is definitely hypertrophied, and infiltrating the wall there are numbers of eosinophils as well as other types of leukocytes.

we have attempted to group forty-one patients according to the most obvious cause of dyspnea. In spite of the fact that each of this series of forty-eight patients had been subjected to a more or less complete post-mortem examination, there remained seven histories in which the data were too meager to permit of classification; forty-one patients, therefore, form the basis for determining the percentage factor indicated in table 2. We are convinced that none of the unclassified patients were typically allergic. Other data relating to these patients appear in figure 4.

The circulatory dysfunctions are arranged in sequence, as are the "diseases of the lungs." One may note that thirteen patients (eight males and five females) were afflicted with a "disease of the heart." They represent 31 per cent of the units presented in table 2. Pulmonary pathologic conditions, exclusive

of allergic asthma, account for sixteen additional cases (ten males, six females), or approximately 40 per cent.

Bronchiectasis is occasionally mentioned as a cause of "asthma" and is commonly thought to result from protracted dyspnea, cough and wheezing. When the patient has an especially productive cough, this diagnosis seems to find added support. It is a characteristic of the groups we have discussed that clinically and grossly bronchiectasis, and also lung abscess, was not conspicuous. Incidental pleural scarring was noted in only a few instances.

Many support the theory that the adrenals or other glands of internal secretion must be abnormal in one who has "asthma," but we find no evidence to support this contention. Unless specifically noted in the

Fig. 8 (case 11, male, fig. 4).—Section of 4 mm. bronchus $\times 85$. Note the ulceration and hyperplasia of the epithelial lining, the thick hyaline basement membrane; hypertrophy and mucinous exudate obstructing the lumen.

abstract, the adrenals at necropsy appeared normal and grossly no thymic tissue was found. Examination of other glands was too cursory to permit any conclusion. In general the degree of arteriosclerosis was not excessive and quite frequently was less than that expected for the chronological age.

In 26 per cent only does the diagnosis of allergic asthma seem tenable; here circulatory dysfunction and pulmonary pathologic conditions were of little or no significance. The absence of those conditions is interesting, since we have just shown that they were of primary importance in 71 per cent of this group. Mechanical factors, distortion of the thorax in one and tracheal compression by an aneurysm in another, account for nearly 5 per cent of the series of forty-one individuals. If one again refers to figure 4, one may be better able to visualize the place, in each male and female group, occupied by those individuals representing 26 per cent of the series. An asterisk appears above the bar representing such patients. It must be again emphasized that we do not accept these as typical

examples of allergic asthma; one or more features make it impossible to exclude that diagnosis. On the same basis the possible examples of allergic asthma, in the group previously published, have been similarly designated.

Attention has been directed to the approximate identity of our two series, those with and those without necropsies, to the group already published. In our group without postmortem examination we find nine male and seven female patients in whom it was impossible to exclude asthma. Here again are instances in which the data were too few to permit of differential diagnosis. It is our contention, therefore, that the trends brought out in table 2 are common to the other subdivisions of the total of 187 patients.

Our emphasis on careful differential diagnosis of "asthma" may seem too academic. This attitude would not, we believe, be shared by the victim of allergic asthma who has been refused insurance or who has been "rated up," in spite of normal physical examinations, because of the supposed excessive risk.

Some may contend that there is no excuse for making a diagnosis of "bronchial asthma" on some of these patients. With this we agree, but the fact remains that they were so diagnosed, not once but usually many times and by different visiting internists. The clinical study, with numerous consultations and roentgenologic, laboratory and other examinations, was more extensive than ordinarily given a private patient. The clinical picture during life and the pathologic examination subsequently formed the basis for innumerable discussions. Our decisions are often at variance with the intern or resident who signed the death certificate. We are willing to concede that the clinical¹⁶ as well as the pathologic criteria are not too well established.

It is frequently stated that one or more signs or symptoms, or the response to a drug, are pathognomonic of allergic asthma. A few of the inconsistencies should convince one that this belief is without basis. Epinephrine may occasionally afford more relief in a cardiac patient than in another with typical allergic asthma. Caffeine, a drug more or less specific for the former, may at times be more effective than epinephrine, and possibly even in a child with allergic asthma. Expiratory dyspnea, frequently emphasized in the allergic type, may at times be more conspicuous in miners' asthma or in cardiac dyspnea. Others hold that fine moist râles are almost pathognomonic of the latter, yet they occur in allergic asthma. Edema of the lower extremity may be entirely postural owing to the patient sitting in a chair day and night for many hours. This may be misinterpreted as circulatory failure.

In spite of an apparently confused situation, there are certain rather definite indexes of allergic asthma. The borderline case will be difficult if not impossible to classify. Since the term asthma tends to convey the idea of a disease entity, we urge that it be discarded or limited to one type. We have quoted several who emphasize the identity of the "bronchial spasm" in all types and who urge the use of the term paroxysmal dyspnea. This could be qualified to indicate an etiologic or other factor. Paroxysmal dyspnea on an allergic basis frequently begins in early life and may be preceded by, or later associated with, one or more allergic conditions—notably allergic vasomotor rhinitis (pollinosis and the like) or eczema. A specific excitant (allergen) may be evident from the history or be deter-

16. One of us (L.) assumes full responsibility for any errors in the evaluation of this factor.

mined by subsequent skin tests. Of some value is the evidence that treatment with the suspected allergen affords relief from, or protection against, symptoms. The evidence is more positive if avoiding contact with the excitant markedly reduces the severity of the asthma. Normal clinical courses interposed between

Fig. 9 (case 13, male, fig. 4).—Section of 3 mm. bronchus $\times 50$, presenting a marked degree of chronic bronchitis.

periods of attacks characterize the condition, at least for many years after onset. The frequency with which one obtains a history of long duration of symptoms is well recognized. This does not entirely exclude the possibility of a fatal outcome after a short duration. A normal or low systolic blood pressure is commonly found even in the older age groups and in spite of years of paroxysmal dyspnea.

A history of this or other allergic conditions in one or more members of the maternal or paternal side or both sides of the family may be of great value; it seems to be present in from 40 to 75 per cent. This wide variation in percentages is probably due to the different standards of what constitutes a positive tendency in the family. With the points we have emphasized, it seems relatively easy to classify, during life, the majority of such patients on the basis of etiology. We have shown that a failure to do this will give one an erroneous idea of the frequency of "diseases of the heart" and "diseases of the lungs." In view of the fact that many of our patients contributed to insurance statistics concerning mortality in "asthma" and that errors in diagnosis of this condition are frequently made by others than our hospital staff, we question the implication that allergic asthma predisposes to "diseases of the heart" or "of the lungs." In substitution for that contention it may be suggested that, as a result of such diseases, wheezing, paroxysmal dyspnea and cough may be conspicuous.

The frequent similarity in the clinical picture, especially in bronchial spasm, in the response to drugs and possibly even in the gross and microscopic postmortem appearances may lead to two opposite points of view. One is that the type of "asthma" is identical in all and that our clinical differentiations are based on incidental observations. One may contend that the only tuberculous (or pneumoconiotic) patient who develops

"asthma," secondary to fibrotic changes in the lung, is one inheriting a tendency to paroxysmal dyspnea. The concept to which we subscribe is that paroxysmal dyspnea, like fever, is a response which may be provoked in most persons, and that the mechanisms behind this are as distinct as are the causes of fever. The absence of a positive family history for allergy in those we believed had allergic asthma is probably due to the patient's incomplete knowledge concerning his family. Skin sensitivity to an allergen may be found in true cardiac dyspnea and bear no relationship to that condition. Further study of pulmonary abnormalities is being carried out in an effort to contribute additional evidence to the solution of these complicated problems.

The earlier literature contains two reports of fatalities from "asthma" in infants and children, and we have collected three in our study. Since our charts were completed, Waldbott¹⁷ has reported two additional cases. He believes that these two cases, more clearly than any other cases on record, represent "asthma" in its most original state. The duration of the dyspnea was three weeks in one patient and six weeks in the other. He somewhat reverses the usual concept of the "thymic death" and wonders whether this condition may be the equivalent of death from asthma in infants. The duration of symptoms in the two previously published was three months and fifteen months respectively. In our series of three patients the duration was one day, one month and five days respectively. Final conclusions are not tenable because of the incomplete data, but we are inclined to believe that the dyspnea and wheezing, especially in the first and third patients, were but symptoms of some primary pathologic con-

Fig. 13 (case 28, male, fig. 4).—Section of 20 mm. bronchus, slightly reduced from a photomicrograph with a magnification of 40 diameters. Note desquamation of epithelium, thin hyaline membrane, apparent hypertrophy of muscle, prominent and numerous glands lined by goblet cells and the leukocytic infiltration containing a few eosinophils, in the wall of the bronchus.

dition of the cardiorespiratory systems. We present these as further evidence that the term "asthma" is misapplied.

CONCLUSIONS

1. The diagnosis of "asthma" is being applied to such unrelated conditions as cardiac dyspnea, mechanical

17. Waldbott, G. L.: Pathologic Changes in Asthmatic Infants, *Am. J. Dis. Child.* 49: 1531 (June) 1955.

obstruction of the trachea, pneumoconiosis and allergic or atopic asthma. Paroxysmal dyspnea better describes the condition and does not commit one to any particular etiology.

2. Concepts based on insurance statistics emphasize the undue predominance of diseases of the heart and lungs in asthma; our studies indicate that such conclusions are due to an inability to correct the crude data. It is therefore incumbent on every physician to use more caution when employing this term.

3. An analysis of the data concerning fifty published case reports with necropsies and our unpublished series of forty-eight cases with and eighty-nine without necropsies show a striking parallelism in the significant features. We construe this to indicate a similarity, if not identity, of the three groups.

4. The hazards of this syndrome (asthma) are more reflected in the statistics for female patients; this agrees with insurance compilations.

Fig. 18 (case 17, female, fig. 4).—Section of 7 mm. bronchus $\times 40$. There are remnants of epithelium overlying a thick hyaline basement membrane. The muscle is moderately hypertrophied. Glands are numerous and prominent. Only a few eosinophils infiltrate the wall.

5. Approximately 40 per cent may survive not more than four years of symptoms. This finding is at variance with accepted clinical concepts regarding true bronchial asthma. An analysis of our unpublished cases with necropsies indicates that not more than 26 per cent actually belong in the latter group and that diseases of the heart or of the lungs are not the result of bronchial asthma.

6. No single clinical criterion seems sufficient to separate the pseudobronchial from the true bronchial asthma, although significant points in differential diagnosis are emphasized.

7. The pathologic appearance in those apparently afflicted with allergic asthma agrees for the most part with that recently emphasized by Macdonald, Michael and Rowe, and others. It is indicated, however, that further study of pathologic changes of the lungs is essential for the establishment of histologic changes pathognomonic of bronchial asthma.

Since patients whose pulmonary tuberculosis is complicated by tuberculous tracheobronchitis have a relatively grave prognosis, the clinical recognition of this complication should be of concern to all phthisiotherapists. In this communication the term "tuberculous tracheobronchitis" denotes a specific infection of the mucosa or submucosa of the trachea and bronchi and is to be distinguished from "tracheobronchial tuberculosis," which signifies clinical tuberculosis of the tracheobronchial lymph nodes.

The pathology of tuberculous tracheobronchitis was accurately described by Carswell¹ and by Louis² nearly a hundred years ago, but contributions to the clinical literature have been few and relatively recent. These have dealt chiefly with patients presenting obstructive respiratory symptoms of varying severity (Schonwald,³ Andrews,⁴ Vinson and Habein,⁵ Ballon,⁶ and others). No textbook on pulmonary tuberculosis has emphasized the frequency or importance of this complication, although Eloesser⁷ called attention to the stenotic forms in 1930 and 1934. During the past six years, increasing clinical experience has enabled us to recognize tuberculous tracheobronchitis more readily and continued observation has given us some knowledge of the course of the disease.

PATHOLOGY

In a necropsy series of 122 cases⁸ (table 1), the predominant mode of mucosal infection appeared to be direct contact with tubercle bacilli from pulmonary cavities. Microscopically the primary tracheobronchial lesions were either minute ulcers in the mucosa or small tubercles presumably resulting from the deposition of tubercle bacilli in the crypts of mucous glands. With progression of the lesions there were submucosal infiltrations with overlying intact mucosa showing edema and congestion or varying degrees of mucosal ulceration. The lesions were characteristically on the posterolateral walls of the bronchi and trachea, further suggesting implantation infection. Occasionally a direct massive extension from a pulmonary cavity to the peribronchial tissues was observed, with subsequent involvement of the mucosa. In the trachea there was no evidence of the mechanism of lymphatic permeation as described by Reichle and Frost⁹ in their cases of tuberculous bron-

The preparation of this report was aided by the Dr. Alexander Fleming Fund for Thoracic Surgery.

chitis. As far as the bronchi were concerned, only about one third of the cases showed evidence that was consistent with a mucosal involvement secondary to tuberculous infection of the peribronchial lymphatics.

There is both pathologic and clinical evidence against the alleged development of tuberculous tracheobronchitis secondary to laryngeal tuberculosis as suggested by Lederer.¹⁰ Out of forty-nine patients in whom a bronchoscopic diagnosis of tracheobronchial disease was made, nearly one half showed no evidence of active laryngeal tuberculosis. In the necropsy series, twenty-two cases showed tracheal or bronchial lesions without laryngeal lesions. Whether or not the larynx showed tuberculosis, there were more instances (twenty-five cases) of bronchial involvement with the trachea free than in the reverse situation (nine cases). This is another indication of the tendency of the infection to come from below.

Statistically considered, the separate percentages of involvement in the larynx, trachea and bronchi are typically those found when three similar events without causal interrelationships arise from a common source; i. e., involvement of all three areas secondary to active pulmonary tuberculosis (figs. 1 and 2).

SYMPTOMATOLOGY

The symptomatology of tuberculous tracheobronchitis is varied, but the persistence of several of the following signs and symptoms may be made the basis for a presumptive clinical diagnosis.¹¹ The clinical syndrome can be conveniently divided into three groups.

The first of these is concerned with the signs and symptoms exhibited by the patient. 1. Persistent inspiratory or expiratory wheezing and rattling, present even after the patient has evacuated all the sputum he can. The wheezing is usually noted by the patient and may be heard by others. It can be elicited by quiet

Fig. 1.—Extensive mucosal tuberculosis of bronchus involving mucous glands and ducts; marked thickening of wall with stenosis of lumen; X 8.

respiration and may be heard by direct auscultation or by placing the stethoscope near the corner of the mouth. This symptom is the one most frequently encountered. 2. Attacks of asthmatoïd breathing with prolongation of one or both respiratory phases. Subjectively the

patient experiences difficulty in getting air "in" and "out," and he may have a sense of substernal constriction. These patients frequently are wrongly diagnosed as having asthma or "asthmatic bronchitis." 3. Persistent parasternal rhonchi, especially in the presence of stenotic lesions.¹² They are best elicited by forced expiration. They may be heard diffusely over the entire

Fig. 2.—Early tuberculous ulceration of mucosa of posterior wall of trachea, superficial type; X 16.

chest but, when localized, the site of the lesion in the tracheobronchial tree may be predicted with reasonable accuracy. 4. Intermittent unexpected elevations of temperature. Sputum retained by an obstructive lesion is often responsible. 5. Paroxysms of violent coughing and choking with unusual difficulty in raising sputum. 6. Dyspnea and intermittent cyanosis on very slight exertion in spite of a vital capacity ordinarily to be considered adequate (1,200 cc. or more). 7. The

* Patients coming to necropsy at the University of Michigan Hospital from 1925 to 1935. The greater frequency of tuberculous mucosal lesions in patients with nonmiliary tuberculosis is well known.

gradual or sudden development of severe obstructive respiratory symptoms with accentuation of wheezing and asthmatoïd breathing. Depending on the location and completeness of the obstruction there are usually secondary signs of lobar or massive atelectasis, as manifested by decreased or absent breath sounds, dullness, mediastinal shift, elevated diaphragm and localized pleuritic pain.

The second group of signs is concerned with characteristics of the sputum which differ from those expected in uncomplicated pulmonary tuberculosis. 1. Excessively large amounts of sputum for the degree of pulmonary tuberculosis visualized roentgenographi-

cally. 2. Exceptionally tenacious, mucoid, "sticky" and "rubbery" sputum. The purulent content is not necessarily high. Frequently the sputum will cling to the bottom of the sputum cup when it is inverted. The patient often experiences difficulty in evacuating this type of sputum. 3. Sputum persistently containing tubercle bacilli in spite of apparent quiescence of the parenchymal pulmonary lesion. 4. Marked variation in the amount of sputum from day to day.

The third group of signs is concerned with the roentgenographic evidences of tuberculous tracheobronchitis. 1. The appearance of intermittent areas of atelectasis in serial roentgenograms of the chest (fig. 3). 2. Sudden lobar collapse following a paralysis of the hemidiaphragm or the induction of pneumothorax is considered highly significant. 3. The visualization of tracheal or bronchial narrowing, particularly in studies made with the Potter-Bucky diaphragm (fig. 4). 4. The occasional demonstration of bronchial stenoses beyond the limits of bronchoscopic vision by brominol bronchograms (fig. 5). This method of examination

scribed submucosal infiltration and thickening and often by submucosal tubercle formation. The overlying mucosa shows edema, chronic congestion and granularity. 2. Hyperplastic, characterized by submucosal proliferation and tuberculoma formation. This process is the same as in 1 but is greater in degree. The inflammatory tissue formation is frequently sufficient to obstruct, partially, the lumen of the trachea or bronchus. 3. Ulcerative, with diffuse or circumscribed loss of mucosa. The ulcers occasionally extend to the cartilage rings. Some patients with predominantly hyperplastic disease show redundant and exfoliative pure tuberculous, or tuberculous and pyogenic, granulation tissue. While ulceration may not be visualized bronchoscopically, the presence of this type of tissue always indicates the loss of mucosal continuity. 4. Fibrostenotic, the frequent result of the fibrotic healing of ulcerative lesions. The stenosis may be localized to one portion of the trachea or bronchus; more often an irregular scar tissue tunnel is found, one or more centimeters in length. In many patients, stenoses are accompanied by

Fig. 3.—Symptomless intermittent atelectasis of the right upper lobe in a patient with tuberculous ulceration of the right stem bronchus. The atelectasis appeared and disappeared four times in nineteen months. A, admission, Nov. 6, 1928; B, Jan. 21, 1929; C, Nov. 5, 1929.

has occasionally been useful when the bronchoscopic examination was negative in the face of strong presumptive clinical evidence of tuberculous tracheobronchitis.

BRONCHOSCOPY

Bronchoscopy is now considered not to be contraindicated in active pulmonary tuberculosis.¹³ At the University of Michigan Hospital, bronchoscopy is employed to confirm the suspected presence of tuberculous tracheobronchitis. Subsequent bronchoscopies may be performed to determine the progression or regression of the mucosal lesions, thus serving as a guide to the treatment of both the tracheobronchial and the pulmonary parenchymal tuberculosis.¹⁴ Diagnostic bronchoscopy is specifically contraindicated by recent hemoptysis, by severe tuberculous laryngeal ulceration and by hopelessly advanced parenchymal tuberculosis.

Bronchoscopically, the following four types of tracheobronchial lesions are recognized, although any patient may show a combination of lesions: 1. Non-ulcerative and nonstenotic, characterized by circum-

residual mucosal ulceration with or without granulation tissue. Occasionally enlarged tracheobronchial lymph nodes by pressure cause narrowing of the trachea or bronchus in the absence of cicatricial scar tissue formation. This, however, is rare in adults and was found bronchoscopically in but two cases in our series. The bronchoscopic picture of a semilunar indentation near the carina and frequently on the posterior tracheal or medial bronchial wall suggests an enlargement of the lymph nodes.

Tuberculous mucosal lesions, whether ulcerative or nonulcerative, are usually found in the upper portions of the stem bronchi on the posterior or posterolateral walls. There is frequent involvement of the orifices of the upper and middle lobar bronchi. Lesions involving the whole circumference of the bronchi are common and, when ulcerative, frequently result in stenosis if healing occurs. Tracheal lesions are found typically in the lower one third on the posterior and posterolateral walls, although ulcers have occasionally been described anteriorly. In the trachea, also, circumferential lesions are common. When the bronchial lesions are unilateral the disease is almost always present on the same side as the more advanced pulmonary parenchymal tuberculosis. It is noteworthy that when the one stem bronchus and the trachea are affected the tracheal

C.: *Bronchoscopy in Tuberculosis*, *Ann. Otol., Rhin. & Laryng.* 43: 1139-1146 (Dec.) 1934.

14. Samson, P. C.: *Tuberculous Tracheobronchitis: The Role of Bronchoscopy*, *Ann. Rev. Tuberc.* 34: 671-699 (Nov.) 1936.

involvement is usually on the posterior and posterolateral quadrant corresponding to the diseased bronchus. Tuberculous lesions are rarely strictly localized but tend to involve several centimeters of the air passages. The change from normal to abnormal mucosa is usually abrupt. A diffuse inflammatory change of the entire tracheobronchial tree is against the lesions' being tuberculous.

The bronchoscopic differential diagnosis lies between nonspecific inflammations and ulcers, erosion of lymphatic glands, syphilis, neoplasm, rhinoscleroma, asthma

and the miscellaneous group of extrabronchial conditions causing obstruction by pressure from without. The latter group includes aneurysm, dermoid tumor, substernal goiter and neoplasms of the vertebral column, esophagus and sternum.¹⁵

The question of biopsy in suspected tuberculous tracheobronchitis is pertinent. In this clinic a biopsy is not made if the lesion is believed to be tuberculous. In our experience an increase in the parenchymal dis-

Fig. 4.—Tracheal narrowing visualized roentgenographically by means of the Potter-Bucky diaphragm, Aug. 22, 1935. The trachea has been shaded. Bronchoscopically there were ulceration of the tracheal mucosa and fibrostenosis.

ease of several patients has been observed following biopsy, probably from hemorrhage, further inflammatory swelling causing obstruction or the aspiration of particulate matter. Furthermore a biopsy of relatively normal mucosa tends to establish an active tuberculous focus owing to the abrupt breaking of the natural defense mechanisms of the body. If the weight of clinical and bronchoscopic evidence is in favor of nonspecific inflammation, syphilis, neoplasm or rhinoscleroma, a biopsy should be made.

PROGNOSIS AND COLLAPSE THERAPY

From the point of view of prognosis, patients with tuberculous tracheobronchitis may be divided into two groups, based on the type of lesion visualized bronchoscopically: 1. The ulcerative and stenotic group. Ulceration is believed to be a late, active manifestation of tuberculous tracheobronchitis and probably indicates grave disease. Patients with stenotic lesions are also included in this prognostic grouping because they often have persistence of respiratory symptoms and occasional exacerbations of parenchymal tuberculosis because of insufficient evacuation of sputum. They commonly have severe reactions following operation. The development of obstructive emphysema or atelectasis and bronchiectasis beyond the stenosis is not uncommon (fig. 6). In one patient death was due directly to the stenosis, which was proved by repeated bronchoscopic examinations to be the result of healing of a diffuse ulcerative lesion. 2. The nonulcerative and nonstenotic group. These lesions are believed to be

relatively less active and perhaps earlier than the lesions in the first group. The hyperplastic cases in which there is no gross ulceration of the mucosa and in which the tissue proliferation is not sufficient to cause marked diminution in the size of the lumen are included.

This study is based on fifty-five patients with a clinical diagnosis of tuberculous tracheobronchitis. In this group six were not examined by bronchoscopy; in two of the six the clinical diagnosis was later verified at necropsy. Twenty-four patients have been followed for one or more years or until death; of these patients, seventeen had ulcerative and stenotic lesions (group 1) and seven had nonulcerative and nonstenotic lesions (group 2). In the first group nine (52.9 per cent) are dead and none have yet returned to complete health. The poor prognosis of patients with ulcerative and stenotic disease is shown in table 2. The majority have been referred from the Michigan State Sanatorium.

A further analysis of the nine deaths shows that five patients died with typical obstructive respiratory symptoms due to the tracheobronchial lesions. In the remaining four the complication of ulcerative tuberculous tracheobronchitis appeared to be a grave manifestation of the patients' poor resistance to tuberculosis. In group 1, sixteen of the seventeen patients eventually received some form of collapse therapy for their parenchymal pulmonary tuberculosis (phrenic nerve paralysis, pneumothorax, multiple intercostal neurectomy, extrapleural pneumonolysis with paraffin filling, thoracoplasty or a combination of these measures). In approximately one half of these patients, symptoms of tracheobronchial disease first appeared following the inception of collapse therapy measures, occasionally even after the parenchymal disease was quiescent. In

the others, however, this complication was diagnosed before any treatment was begun. Collapse therapy is most probably not a responsible etiologic agent. Formerly it was customary to treat the pulmonary disease by whatever collapse therapy operation seemed indicated, without regard to the known presence of ulcerative or stenotic tracheobronchitis. Many of these patients had extreme difficulty in raising sputum postoperatively, the symptoms of respiratory embarrasment

Fig. 5.—Bronchogram showing a stenosis of the left upper lobe bronchus which could not be seen bronchoscopically because the lesion was "around the corner" (Oct. 27, 1935). The patient had choking attacks, with great difficulty in raising sputum, and intermittent dyspnea and cyanosis. The vital capacity was 1,700 cc.

were aggravated and approximately one half eventually died. In general, equally poor results were obtained whether the patient was treated by bed rest alone or by collapse therapy, and whether the designated treatment was instituted before or after the appearance of symptoms of tracheobronchial disease.

Because of the obviously poor prognosis we do not now recommend any type of collapse therapy for

15. Furstenberg, A. C.: Personal communication to the authors, Aug. 25, 1935.

patients with ulcerative tracheobronchial lesions unless subsequent bronchoscopic examinations demonstrate a tendency for the ulcers to heal without the formation of an important stenosis. Major collapse measures are of no benefit to ulcerative and stenotic tuberculous tracheobronchitis. The control of the parenchymal lesion is insufficient, since ulcerative disease, when once established, is frequently self propagating.

The symptoms in nonulcerative and nonstenotic tuberculous tracheobronchitis (group 2) are not striking and the clinical and bronchoscopic recognition of this

factors of specific tissue resistance and susceptibility to tuberculosis as far as they concern the tracheobronchial mucosa.

TREATMENT

The varied types of therapy employed in this and other clinics are indicative of the poor results obtained in the treatment of patients with tuberculous tracheobronchitis. When we first began to recognize these cases their similarity to asthma and other allergic states led to the symptomatic use of atropine, epinephrine, ammonium chloride, autogenous sputum vaccines and protein sensitization therapy. None of these measures were more than temporarily effective in relieving symptoms. The temporarily favorable effect of epinephrine was probably due to a decrease in obstruction through a lessening of the vascular congestion in the lesions. Other methods of general treatment have been attempted. A change to a high, dry and warm climate or to a cold climate has not proved successful in relieving symptoms. Ultraviolet rays and tuberculin therapy have been employed without beneficial effect.

In selected cases bronchoscopy has given striking symptomatic relief. Patients with nonulcerative and hyperplastic disease occasionally have difficulty in raising sputum because the diameter of the tracheobronchial lumen is decreased by mucosal edema and congestion. When this condition is encountered bronchoscopically, careful chemical shrinkage of the edematous mucosa (equal parts of 10 per cent cocaine hydrochloride and 1:1,000 epinephrine hydrochloride) often produces excellent results. Patients who have severe respiratory distress may be temporarily relieved by the bronchoscopic aspiration of obstructing tenacious secretions, mucous plugs or crusts. This procedure may be an immediate life-saving measure but usually is only palliative. Tracheotomy has been necessary three times because of postbronchoscopic laryngeal edema. Repeated low bronchoscopic and catheter aspirations were facilitated, but tuberculous wound infections and inability to raise sputum efficiently were serious post-operative complications, and all three patients eventually died.

The treatment of cicatricial stenoses must be individualized. Localized stenoses of the stem bronchi may be carefully dilated by repeated bronchoscopic bougi-

Fig. 6.—The development of diffuse tuberculous bronchiectasis in a patient with chronic ulcerative and stenotic tuberculous tracheobronchitis. A, cross-section of trachea just above the carina, showing thickened sclerotic wall. B, cross-section of right stem bronchus, showing thickening of its wall. C, cross-section of left stem bronchus, showing marked obstructive fibrosis. D, longitudinal section of left lung, which had been subtotally collapsed by induced pneumothorax for two years prior to death. At necropsy each bronchiectatic cavity contained an occluding, extremely tenacious, mucous and fibrin cast.

type of lesion has been relatively recent at this clinic. After observing several of these patients over a considerable period we came to believe that this type of the disease was relatively less active and virulent than was the ulcerative type. Consequently collapse therapy has been instituted as indicated for the parenchymal tuberculosis. In this group of seven patients, none are dead and four have closed cavities and negative sputum fol-

* G. L. Leslie and R. S. Anderson's (personal communication to the authors, Oct. 25, 1935) statistics for resident and discharged patients over a recent four and one-half year period. All patients with known tuberculous tracheobronchitis have been excluded from these figures.
† One patient in this group had no roentgen evidence of parenchymal disease when the diagnosis of tuberculous tracheobronchitis was first made; one patient had had minimal pulmonary tuberculosis when first seen and she subsequently died. At the time they entered a sanatorium, however, both had moderately advanced pulmonary tuberculosis.

lowing thoracoplasty. Three are unimproved and have intermittently positive sputum: In two of them phrenic nerve interruption was used, and in the other pneumothorax. It is impossible, however, to predict whether nonulcerative tracheobronchial lesions will remain quiescent following control of the parenchymal tuberculosis. We feel that some such lesions will inevitably progress to ulceration and, perhaps, to stenosis. At the present time, careful clinical and bronchoscopic reexaminations can be our only guides, and until further data are available we cannot evaluate the intangible

nage if no active mucosal disease is demonstrable. Patients frequently lose all symptoms of wheezing and difficulty in raising sputum after a series of successful dilations. In the presence of extensive mucosal inflammation or ulceration, mechanical dilation or even the trauma of passage of the bronchoscope past the lesions is likely to be harmful. On four occasions nearly complete obstruction has resulted from an acute exacerbation of edema and congestion in already inflamed tissues. Tracheal stenoses are more serious than bronchial stenoses and in our experience any attempt at local treat-

ment has led to uniformly bad results. Dilation or the forced passage of a small bronchoscope should not be attempted unless there is impending suffocation.

If a small, sharply circumscribed tuberculous ulcer should be discovered, consideration might be given to its treatment by electrocauterization with the high frequency current, as similar lesions in the larynx are often treated.¹⁶ Since such a strictly circumscribed lesion seldom occurs, this therapeutic consideration is based on theoretical grounds alone.^{16a}

Roentgen therapy in divided doses was proposed by Jacox¹⁷ as a possible means of treating active tuberculous mucosal lesions on the basis that early induction of fibrosis might aid in healing, similar to the reported action of irradiation in tuberculous lymphadenitis.

The x-ray beam is directed through two ports, from 10 to 12 cm. square, centered over the lesions as localized bronchoscopically. One port is on the anterior and one on the posterior surface of the chest. The ports are treated alternately at weekly intervals, and the irradiation is continued until a definite erythema develops. This usually occurs after from six to eight treatments have been given. The physical factors are as follows: filtration, 0.25 mm. of copper and 1 mm. of aluminum; voltage, 150 kilovolts (Villard circuit); tube current, 25 milliamperes; skin target distance, 50 cm.; intensity of irradiation, from 34 to 39 roentgens per minute, measured in air without backscatter; dosage per treatment field, from 200 to 300 roentgens.

Since the treatment is experimental to a large extent, a critical evaluation of results is not justified. Eight patients have had their series of treatments completed for three months or longer. In five of the eight who had chronic hyperplastic and ulcerative lesions, bronchoscopic reexamination showed that the active lesions had regressed, although two patients with preexisting fibrostenosis have had evidence of increased scar tissue obstruction. The remaining three of the eight patients were not benefited by irradiation. One of these has shown bronchoscopically a progression of the hyperplastic disease and the recent formation of ulcers. The second had acute, extremely active hyperplastic and ulcerative disease of the lower trachea and left stem bronchus. Obstruction and sudden atelectasis of the left lower lobe followed the fifth treatment, presumably from reactionary edema and congestion of the actively diseased mucosa. The third had tracheal ulceration and moderate fibrostenosis (fig. 4). There was temporary complete relief from symptoms for two months following irradiation, but the severe dyspnea, choking attacks and asthmatic breathing have recently returned.

SUMMARY

1. A positive diagnosis of tuberculous tracheobronchitis has been made in fifty-five patients, twenty-four of these having been observed for a year or longer. On the basis of the type of lesions seen, the patients have been divided into two clinical groups which are of prognostic significance: group 1, ulcerative and stenotic, seventeen patients; group 2, nonulcerative and nonstenotic, seven patients.

2. Of the seventeen group 1 patients, none have yet returned to complete health and nine (52.9 per cent) are dead. Major collapse therapy for parenchymal pul-

monary tuberculosis has had no favorable effect on the ulcerative tracheobronchial lesions of this group.

3. Nonulcerative and nonstenotic tuberculous tracheobronchitis is considered relatively less active than ulcerative disease. For this reason collapse therapy has been recommended as indicated for the parenchymal tuberculosis. Four of the seven patients have had thoracoplasty and now have closed cavities and negative sputum. The other three have intermittently positive sputum and the relationship of this to tracheobronchial disease is not clear. Temporary paralysis of the hemidiaphragm was used in two and pneumothorax in one.

4. In selected cases symptomatic improvement has followed the bronchoscopic aspiration of retained secretions, chemical shrinkage of the edematous mucosa or the careful dilation of circumscribed bronchial stenoses.

5. Of twelve patients who have had a series of roentgen treatments, eight have been followed for three months or longer. The majority of those whose lesions were chronic, hyperplastic and granulo-ulcerative showed a regression of the disease when reexamined bronchoscopically.

6. Because of the poor results obtained in the past, we are not now recommending any type of major collapse therapy for parenchymal tuberculosis in the presence of ulcerative tuberculous tracheobronchitis unless, after bronchoscopic reexamination, it is apparent that the ulcerative lesions are healing without the formation of highly obstructive fibrosis.

THE USE OF SULFANILAMIDE IN GONOCOCCIC INFECTIONS

PRELIMINARY REPORT

JOHN E. DEES, M.D.

AND

J. A. C. COLSTON, M.D.

BALTIMORE

During the past two years, numerous reports have appeared in the European literature regarding the action of para-aminobenzenesulfonamide (sulfanilamide) and its related compounds marketed under the proprietary names of Prontosil,¹ Prontylin and many other names, on both experimental and clinical infections with beta-hemolytic streptococci. Mice are protected or their survival periods significantly lengthened against many lethal doses of this organism by the administration of these drugs. The results of their use in clinical infections have been most striking. Colebrook^{1a} has reported a series of thirty-six cases of puerperal infection with hemolytic streptococci, treated with prontosil. From this he concluded that the drug caused a definitely beneficial effect, as evidenced by a prompt improvement in symptoms, a drop in temperature and a reduction in the death rate from between 18 and 28.8 per cent to 8 per cent in his series.

The first American report was recently made by Long and Bliss,² in which their carefully controlled experimental and clinical studies corroborate and amplify many of the previous experiences. They point

From the Brady Urological Institute and the Johns Hopkins Hospital. Dr. Perrin H. Long assisted with advice and criticism in carrying out this investigation.

Owing to lack of space, reports of illustrative cases have been omitted. The complete article appears in the authors' reprints.

1. The name Prontosil has been used for several related substances that are not identical.

1a. Colebrook, Leonard, and Kenny, *Méave*: *Lancet* 1:1297 (June 6) 1936.

2. Long, P. H., and Bliss, Eleanor, A.: *Para-Amino-Benzene-Sulfonamide and Its Derivatives*, J. A. M. A. 108:32 (Jan. 2) 1937.

16. Terry, G. H. B.: *Electrosurgery in Laryngeal and Pharyngeal Tuberculosis*, South. M. J. 28:509-511 (June) 1935.

16a. Since the preparation of this report the lesions of several patients have been successfully treated by electrocauterization. The method apparently warrants much consideration.

17. Dr. Harold Jacox was formerly assistant professor of roentgenology in charge of therapy at the University of Michigan Medical School and at present is director of the radiation therapy division at the Western Pennsylvania Hospital, Pittsburgh.

* Since the paper was sent for publication, twenty-eight additional cases (to May 12) have been examined and placed under treatment as outlined. In summary to date, then, we have had forty-seven cases of various types of gonococcal infection of the genito-urinary tract. In thirty-six cases the gonococci and the urethral discharge disappeared in less than five days. In five cases the subjective symptoms disappeared completely; there was a marked diminution in the amount of the urethral discharge, but the gonococci were still present. In three cases there was no demonstrable response to the drug in that the symptoms persisted, there was no diminution of the discharge and many gonococci were present. In three cases there was a prompt response to the drug, but as treatment

was discontinued there was a recurrence of the infection. In two of these cases the infection disappeared following a second course of sulfanilamide. The most striking feature of our experience with these forty-seven cases has been that in no instance has there been a progression of the infection, even in the cases which showed no response to treatment. We realize that these cases have not been followed over a long period of time and in some instances the individual patients have failed to return for check up, so that the possibility of late recurrence in at least some of these patients cannot be definitely excluded. In the patients who have returned for check up, however, there has been no recurrence, except in the three instances mentioned.

out that infection with the hemolytic streptococcus, or changes brought about by the infection (probably a chemical reduction), is necessary for the activation of sulfonamide against the organism. Nineteen cases of beta hemolytic streptococcus infection of various types treated with these drugs are reported with dramatic improvement in the majority of cases.

In 1936 Buttle and his co-workers³ in connection with Proom reported that sulfanilamide exerted a marked protective action against meningococcic infection in mice. More recently, Proom⁴ has reported his results and states that "in mice infected with a suspension of meningococci in mucin, Prontylin protects up to one million lethal doses under optimum conditions." Schwenkter,⁵ in a recent report, presents a series of eleven cases of clinical meningococcic infection with sulfanilamide in which there was one death. He concludes that the treatment is as effective as that with antimeningococcic serum.

Marshall⁶ has devised a simple and accurate method for quantitative determination of the amount of sulfanilamide present in the blood, urine and other body fluids and has pointed out much about its fate in the body. He shows that it is rapidly absorbed from the gastro-intestinal tract, enters practically all the body fluids and is excreted rapidly and almost entirely by the urinary tract both in unchanged form and conjugated with an acetyl radical. Retention of the drug in the blood occurs in cases of renal impairment.

Justina H. Hill⁷ has found that the urine of patients excreting sulfanilamide has no bactericidal activity against beta hemolytic streptococci.

Sulfanilamide is relatively nontoxic, some patients tolerating 1 Gm. for 20 pounds (9 Kg.) of body weight daily for as long as a month without serious ill effects. A feeling of lassitude and dizziness is not uncommon during treatment. Colebrook reports several cases of sulfhemoglobinemia, which occurred in cases in which saline cathartics were given during administration of Prontosil. Sporadic cases of leukopenia have occurred, but none of these have been directly attributable to the drug. Acidosis, fever or a condition resembling methemoglobinemia may occur but are quickly relieved by appropriate therapy or reduction in dosage. While no serious toxic effects have been reported, it is obvious that patients must be kept under close medical observation during treatment.

The close biologic relationship between the meningococcus and the gonococcus is well known. It is difficult, however, to infect experimental animals with the gonococcus. It was therefore suggested to us by Dr. Perrin Long that the effect of sulfanilamide on clinical gonococcic infections be investigated directly without preliminary animal experimentation. An analysis of the result of oral administration of sulfanilamide in nineteen cases of gonococcic infection seen in the Brady Urological Dispensary of the Johns Hopkins Hospital is the basis of this report.

CLINICAL INVESTIGATION

Diagnosis.—The diagnosis of gonococcic infection was made on the demonstration of gram-negative intra-

cellular diplococci of typical morphology and distribution in the stained smear of urethral discharge or of the sediment from centrifugated urine. The smear was examined in practically all cases by two observers, and, in case of disagreement, cultures for the gonococcus were made. The diagnosis of posterior urethritis and cystitis were made by a correlation of the symptoms and the results of the three glass test. In some cases a diagnosis of acute or subacute prostatitis was possible on rectal palpation. A few patients were known to have had a chronic prostatitis before treatment was started.

Treatment.—With a few exceptions, all patients received, in four divided doses a day, 4.8 Gm. of sulfanilamide daily for two days, 3.6 Gm. daily for three days, and then 2.4 Gm. daily for from four to eight days. No other treatment, either local or general, was used. Fluids were not forced, as it was thought that this would hasten the elimination of the drug. Alcohol and sexual activity were prohibited. The patients were seen every two or three days during treatment, with few exceptions. Careful examination of the urine for pus and organisms was made on each visit. Cultures for gonococci and stained smears from the fossa navicularis were done whenever indicated.

The accompanying table briefly summarizes the results of examination and the clinical course of all our cases of gonococcic infection that have been followed for five days or more after beginning treatment with sulfanilamide.

There are, for analysis, nineteen cases of gonococcic infection which have been treated with sulfanilamide. Of these, the active urethral discharge disappeared in three cases in one day, in seven cases in two days, in two cases in three days, in two cases in seven days. In one case it disappeared in four days to recur slightly on the fourteenth day and again disappeared on the sixteenth day. One patient was treated for two days with sulfanilamide but failed to return until three days later, during which time no treatment was taken. The discharge had continued during this time. The drug was again administered for two days but the patient did not return until the twentieth day, at which time the discharge was still present and positive for gonococci. The drug was again administered and the discharge disappeared and the smear became negative for gonococci in the ensuing three days and has not recurred to date. The patient has now been seen twenty-four days since the treatment was discontinued; there is no discharge present and the urine is clear. In two cases the discharge is still present ten and twelve days respectively after the beginning of treatment. One patient, with chronic anterior and posterior urethritis, subacute prostatitis, subacute right epididymitis and acute left epididymitis had no urethral discharge, but gonococci were demonstrated on smear and culture from the urine. The organisms disappeared three days after the institution of treatment, and there had been marked diminution in the swelling of the left epididymis. The urine was hazy in the first glass, the second and third glasses were clear, and the patient's symptoms had disappeared. When seen last on the fourteenth day after the institution of the treatment, the patient was free from symptoms, there was no urethral discharge and the urine was clear in three glasses. Prostatic secretion showed from 6 to 8 white cells per high power field.

Stained smears from the urethral discharge and centrifugated urine became negative for gonococci (to date) in five cases in two days, in five cases in three

communication to the authors.

days, in two cases in five days, and in one case each in four, six and twenty-three days. In one case smears became negative on the ninth day, positive on the fourteenth day and again negative on the seventeenth day. In three cases gonococci are still present after eleven days.

Symptoms of burning and frequency disappeared in two cases in one day, in eight cases in two days, in two cases in three days, and in one case each in four, five, seven and eight days. There is no note on the history in three cases.

Symptoms of slight dizziness and lassitude occurred in four cases with the initial larger doses but disappeared when the amount of the drug was reduced. One patient had fever, general malaise and sulfhemoglobinemia for two days, but these symptoms disappeared within twenty-four hours after medication was discontinued.

Two patients with known preexisting chronic prostatitis and two patients with subacute prostatitis were found to have a normal prostatic secretion after treatment for from ten to twelve days. In three other cases of subacute prostatitis at the beginning of treatment, one subsequently showed from 6 to 8 white blood cells per high power field, one showed a few clumps of pus, and in the third the pus was only slightly reduced in six days.

In several instances it was noted that, as the urethral discharge began to disappear, the gonococci were found to lie extracellularly, with little or no evidence of phagocytosis by the leukocytes.

Five or six of the cases showed a much slower response to the administration of sulfanilamide than did the others, and we felt that three or four were little if any benefited by the drug. The reason for such failures is not clear. One of the patients had a very small amount of the drug during the first five days and another did not return for fifteen days during the early treatment. The others of this group were quite conscientious in attending the clinic and obeying instructions. Estimations of the concentration of sulfanilamide in the blood have not been made on these patients. It is possible that some abnormality in the metabolism of sulfanilamide in these particular individuals may explain some of the failures.

The use of sulfanilamide in gonococcic infections is as yet in an entirely experimental state. Nevertheless the surprisingly prompt response to treatment in the majority of our cases has deeply impressed all those who have seen them. The prompt disappearance of urethral discharge and symptoms of burning and frequency have been most striking, especially when contrasted with the clinical course of patients treated with the usual methods heretofore in use. It has been especially impressive to us that the infection in none of our treated cases has progressed from anterior to posterior urethritis or from posterior urethritis to prostatitis or epididymitis after the institution of the treatment.

While only one of our cases in which the discharge had been absent for a period of a week has shown a recurrence of the infection, it must be realized that larger series of cases must be followed over a longer period of time before a complete evaluation of sulfanilamide in the treatment of gonococcic infections can be determined. Further studies must also be made to determine the optimum dosage and the length of time during which treatment should be continued.

An emphatic warning should be sounded as to the possibility of reactions from this drug, as should be done of course in the clinical use of any new drug or treatment. Immediately on the complaint by the patient of lassitude or dizziness, the dosage must be reduced or the drug discontinued completely. We have observed no serious symptoms. Should symptoms persist, a complete blood study should be done.

Our relatively brief experience with the use of sulfanilamide in the treatment of gonococcic infections has led us to believe that this drug will prove of great value. The prompt response to treatment in the vast majority of our cases, the smooth clinical course, the fact that no complications have occurred and that the infection has not progressed, together with the reduction in hospital expenses from the use of the necessary drugs and medicaments previously used in the treatment of this type of infection, have impressed us profoundly. This preliminary report is therefore presented for the purpose of stimulating the careful use of this drug in clinics where large numbers of gonococcic infections can be closely followed, so that an accurate evaluation of sulfanilamide in the treatment of gonococcic infections can be determined and the optimum dosage and possible deleterious effects further studied.

EXPERIMENTAL STUDIES WITH SULFANILAMIDE AND WITH PRONTOSIL

IN HEMOLYTIC STREPTOCOCCUS INFECTIONS

RALPH R. MELLON, M.D.

PAUL GROSS, M.D.

AND

FRANK B. COOPER, M.S.

PITTSBURGH

The results obtained by the use of sulfanilamide and of prontosil¹ in the treatment of infections produced by hemolytic streptococci,² and, to a lesser degree, of infections produced by type III pneumococci,³ leave no doubt as to the therapeutic efficacy of these compounds; but at the same time an adequate explanation of the mechanism of their action is lacking.

Colebrook, Buttle and O'Meara⁴ found sulfanilamide to be bactericidal against the hemolytic streptococcus in vitro and, to a limited degree, in vivo. They also recognized a discrepancy between the remarkable therapeutic results obtained and the limited bactericidal activity observed and suggested that the enhanced bactericidal action of the blood was supplemented by that of the tissues of the whole animal. Long and Bliss,⁵ on the other hand, considered the stimulation of phagocytic activity of the polymorphonuclear leukocytes and of the monocytes of paramount importance in the mechanism of action of these drugs.

From the Institute of Pathology, Western Pennsylvania Hospital. Read in abstract form before the annual meeting of the Society of American Bacteriologists, Indianapolis, Dec. 30, 1936, and before the Allegheny County Medical Society in January 1937.

1. In this paper prontosil refers to the disodium salt of 4-sulfamidyl-phenyl-2-azo-7-acetylamino-1'-hydroxynaphthalene-3', 6' disulfonic acid, a product of Winthrop Chemical Company.

A second point of interest is the paradoxical situation first mentioned by Nitti and Bovet⁶ and subsequently confirmed by Colebrook and Kenny,⁷ as well as by Long and Bliss;⁵ namely, that, while good therapeutic results were obtained with these drugs in mice infected with hemolytic streptococci of high virulence, little if any effect was obtained with strains of low virulence.

In this paper we are reporting the results obtained by treating mice infected with hemolytic streptococci of different virulence levels with sulfanilamide and with prontosil. The data obtained have a bearing on the points of interest just mentioned.

Two strains of hemolytic streptococci were used: the "Stoddard" strain, isolated from a case of septicemia at the Western Pennsylvania Hospital, and the "Pion" strain, which was obtained from the Pasteur Institute. The former had spontaneously acquired high virulence without animal passage and was used at the time of maximal virulence and also during a period of spontaneously diminishing virulence. The latter culture was considered moderately virulent.

NO. 1. STODDARD CULTURE OF HIGH VIRULENCE

The effect of prontosil and sulfanilamide was determined on mice infected with approximately 1,000 minimum lethal doses (determined prior to and at the time of the experiment) and initial treatment was begun after the expiration of various intervals.

Seventy-two mice were infected intraperitoneally with 0.5 cc. of a 10^{-6} dilution of a sixteen hour broth culture of the Stoddard strain (in its mucoid phase) and were divided into nine groups of eight mice each, as shown in charts 1 and 2. Group 1 served as untreated controls, while groups 2, 3, 4, 5 and 6 were given 10 mg. of prontosil subcutaneously two, four, six, eight and ten hours respectively after infection. The remaining three groups (7, 8 and 9) were given 25 mg. of sulfanilamide by mouth six, eight and ten hours

Chart 1.—Stoddard (mucoid) 0.5 cc. of 1:1,000,000 sixteen hour broth culture. The prontosil used is the disodium salt of 4-sulfamidophenyl-2'-azo-7'-acetyl-amino-1'-hydroxynaphthalene-3', 6' disulfonic acid.

respectively after infection. Further treatment of the animals is indicated in the graphs.

The resulting fatalities came to autopsy; sections were made of the livers, and spleens and smears of the peritoneum and heart blood were stained by the Gram method. Many cultures were also made.

6. Nitti, F., and Bovet, D.: Compt. rend. Soc. de biol. **119**:1277, 1935.

7. Colebrook, Leonard, and Kenny, McEave: Lancet **1**:1297 (June 6) 1936.

While all the control mice died within two days, the mice treated with prontosil showed a marked increase in survival time, as clearly indicated in chart 1. The average survival time varied with the different prontosil treated groups and could not be correlated with the lapse of time between infection and initial treatment.

Chart 2.—Stoddard (mucoid) 0.5 cc. of 1:1,000,000 sixteen hour broth culture.

Despite continued treatment, all animals ultimately died of the infection. Postmortem examinations were uniform and showed streptococci in the peritoneum and in the heart blood of every animal.

Reference to chart 2 indicates that the mice treated with sulfanilamide six hours after infection showed 50 per cent survival; in the eight hour group 25 per cent survival, and no survivals in the group in which treatment was delayed until ten hours after infection. Stained smears and cultures of the peritoneal cavity, blood, spleen and liver of animals that were killed after twenty-five days were consistently negative.

NO. 2. STODDARD STRAIN (HIGH VIRULENCE, OVERWHELMING DOSE)

While this culture was at the height of its virulence, an additional series of thirty mice was infected with about 200,000 minimum lethal doses. Ten were treated with sulfanilamide and ten with prontosil, as indicated in chart 3. While the treated animals lived longer than the controls, all of them died of streptococcic peritonitis and septicemia.

NO. 3. STODDARD CULTURE OF MODERATE VIRULENCE

A series of forty mice was infected intraperitoneally with 0.5 cc. of a 10^{-5} dilution of a nineteen hour broth culture of the Stoddard organism in its mucoid phase. Since a marked drop in virulence had occurred, this dose represented approximately 10 minimum lethal doses (determined by previous and simultaneous titra-

tions). Ten of these mice served as untreated controls; ten were given an initial dose of 25 mg. of sulfanilamide; ten received 6.25 mg. of the same drug, and ten mice were given 6.25 mg. of prontosil. All drugs were given by mouth within half an hour after infection. Daily oral treatments of 6.25 mg. of the respective drugs were administered for nine consecutive

Chart 3.—Stoddard (mucoid) 0.5 cc. of 1:5,000 seven hour broth culture.

days, after which all treatment was discontinued. The results (chart 4) indicate 100 per cent recovery in each of the three treated groups, against 90 per cent fatality in the control group.

NO. 4. PION STRAIN (MODERATE VIRULENCE)

The virulence of this strain was such that 0.5 cc. of a 10^{-3} dilution of an eighteen hour broth culture killed 20 Gm. mice in about ninety hours. Thirty mice were infected with this amount and treated as indicated in chart 5. Whereas nine out of ten of the controls died, the sulfanilamide treated group showed 60 per cent recovery, and the prontosil treated group 30 per cent recovery.

PHAGOCYTIC ACTIVITY OF WHITE BLOOD CELLS AND OF RETICULO-ENDOTHELIAL CELLS

Smears from the peritoneal exudate, as well as histologic sections of the liver and spleen of mice of the various experiments, were examined for evidence of phagocytosis. A polymorphonuclear leukocyte which contained a few streptococci was found occasionally in the controls and less frequently in the treated animals. The reticulo-endothelial cells of either the treated or the control groups showed little or no indication of phagocytosis.

NO. 5. CIRCUMSCRIBED FOCI OF INFECTION

Six guinea-pigs of about 400 Gm. weight were given three simultaneous 0.1 cc. intradermal injections of undiluted, virulent Stoddard culture. Three of these animals had received 500 mg. of sulfanilamide by mouth four hours prior to infection, followed by a second dose of 300 mg. on the second day, and a third dose of 250 mg. on the fourth day. Representative lesions were excised after one, two, three and five days respectively from both treated and untreated animals. Sections were made and stained with hematoxylin and eosin and by the Gram method.

A second series of six guinea-pigs (average weight 250 Gm.) were given two simultaneous intradermal 0.1 cc. injections of a 1:10 dilution of a twenty-four hour culture of the same strain. The three animals that

had received 250 mg. of sulfanilamide by mouth four hours previously were subsequently given the same oral dose on the second, fourth and fifth days respectively.

The injections in the first series resulted in every instance in the production of erythematous, indurated lesions which rapidly became pustulous and ulcerated. The lesions of the treated animals were smaller and more sharply circumscribed; the ulcers were more superficial and healed quickly. The lesions of the untreated guinea-pigs were larger and more diffuse, and some were associated with secondary purulent folliculitis, which eventuated in the death of the animals from streptococcal septicemia on the fourth, eighth and fourteenth days respectively. One of the treated animals of the first series succumbed on the eighteenth day to streptococcal septicemia, while the other two survived.

The guinea-pigs in the second series showed similar but more marked differences between the lesions of the treated and those of the untreated animals. Microscopic sections of the biopsies, regardless of age or treatment, showed masses of streptococci in the deeper tissues as well as near the surface of the skin. No apparent qualitative difference in histologic response to the organism as the result of treatment could be detected. There was no greater phagocytic activity in the lesions of the treated animals than in those of the controls.

COMMENT

It is not unlikely that differences inherent in the cultures employed may be an important factor in explaining the discrepancies between our observations and those of Long and Bliss⁵ regarding the rôle of phagocytosis in the mechanism of the action of these drugs. A streptococcus in the mucoid phase, such as we employed, is well understood to be highly resistant to phagocytosis—at least until it is sensitized by the opsonizing powers of the blood. At any rate, our

Chart 4.—Stoddard (mucoid) 0.5 cc. of 1:100,000 nineteen hour culture (intraperitoneal).

therapeutic results must find explanation in some other defense mechanism than phagocytosis.

The foregoing guinea-pig experiments also indicate that the drugs do not alter the qualitative character of the tissue response to the hemolytic streptococcus. The presence of masses of streptococci in the deeper tissues of both treated and untreated animals alike, regardless of the time at which they were examined, does not speak favorably for the assumption of Colebrook and his co-workers⁴ that the mechanism of action of the sulf-

sulfanilamide compounds consists of the bactericidal action of the blood, supplemented by that of the tissues of the whole animal.

It is unfortunate that these experiments do not throw any light on the mechanism of action, except in a negative way.

Our favorable therapeutic results with hemolytic streptococcus cultures of medium virulence are at variance with the results of other investigators.⁸ It is possible that these divergent results may be explained by differences in the infecting doses. Our infecting doses were from 1 to 10 minimum lethal doses, whereas either the dosage was not indicated in the reports that cited negative results or it was greater than ours.

CONCLUSIONS

1. Both sulfanilamide and prontosil exhibit marked therapeutic effects in mice against hemolytic streptococcus infections.

Chart 5.—Pion strain 0.5 cc. of 1:10,000 eighteen hour broth culture.

2. This effect obtains for strains of both medium and high virulence.

3. Our experiments show no indication that phagocytosis is a factor in the mechanism of the therapeutic action of these drugs.

4. Proper treatment of guinea-pigs with sulfanilamide results in a localization and rapid healing of experimental intradermal hemolytic streptococcus infections, which in the untreated animal may disseminate with fatal results.

5. No qualitative changes in the character of the histologic response to the hemolytic streptococcus as a result of sulfanilamide administration have been noted.

COOPERATIVE CLINICAL STUDIES IN THE TREATMENT OF SYPHILIS

THE EFFECT OF SPECIFIC THERAPY ON THE PROPHYLAXIS AND PROGRESS OF CARDIOVASCULAR SYPHILIS

HAROLD N. COLE, M.D.

CLEVELAND

WITH LIDA J. USILTON, M.A., WASHINGTON, D. C.; JOSEPH EARLE MOORE, M.D., BALTIMORE; PAUL A. O'LEARY, M.D., ROCHESTER, MINN.; JOHN H. STOKES, M.D., PHILADELPHIA; UDO J. WILE, M.D., ANN ARBOR, MICH.; THOMAS PARRAN JR., M.D., ALBANY, N. Y., AND JOHN McMULLEN, M.D., WASHINGTON, D. C.

The method of isolation of *Spirochaeta pallida* by means of the darkfield and a specific treatment for early syphilis have been available for more than twenty years. Yet even now, incidence studies¹ throughout the United States indicate that one half of the infected population neglect treatment until late or crippling manifestations force them to seek medical care. Therefore it is of paramount importance that not only the apparent late conditions such as dementia paralytica and tabes be recognized, but also the sometimes cryptic late conditions such as cardiovascular syphilis. The medical profession is well aware of the many cases that escape the clinical observation of the physician and all too frequently come to autopsy with undiagnosed cardiovascular syphilis. Every effort should be made to recognize the existence of syphilitic cardiovascular involvement while in the stage of uncomplicated syphilitic aortitis before the development of irreparable anatomic or functional damage to the heart.

INCIDENCE

Annually in the United States nearly a half million people with late syphilis seek treatment for the first time, approximately 50,000 of whom have obvious cardiovascular syphilis on admission.

From a pathologic point of view Warthin,² using both gross and microscopic criteria, found specific cardiovascular changes in from 86 to 98 per cent of patients with syphilis, while Langer³ in the 23,105 autopsies of the Virchow Krankenhaus found that from 70 to 80 per cent of the syphilis cases showed cardiovascular involvement. Guldberg,⁴ in a survey of 8,235 autopsies at Harbitz Pathologic Clinic in Oslo, found that more than 58 per cent of 481 cases of syphilis showed evidence of vascular involvement. In 261 cases it was the primary condition and among these it was the cause of death in 218.

The point has been made by several writers that the higher incidence of cardiovascular syphilis may be due to modern methods of therapy with arsenicals. The

report of the German and Russian syphilis expedition⁵ to Burjat, Mongolia, for the study of virgin syphilis showed that cardiovascular syphilis was as frequently noted as in Berlin material treated with arsenicals and heavy metal. Moreover, in the Cooperative Clinical Group study⁶ 69 per cent of the cardiovascular syphilis cases had had no previous treatment or only a little heavy metal and for cases of syphilitic aortitis with aneurysm this percentage was as high as 84. Thus one is forced to the conclusion that it is not treatment but the lack of it that predisposes the patient to syphilitic cardiovascular involvement. Analysis of those cases in which cardiovascular syphilis developed despite adequate treatment showed that, with the exception of two of the 640 cases of cardiovascular syphilis, treatment had been very irregularly given or had been delayed until syphilis had reached the late stages.

DIAGNOSTIC METHODS

The principal symptoms and signs in the records of cases of cardiovascular syphilis diagnosed as uncomplicated syphilitic aortitis in the Cooperative Clinical Group material are given in the order of their importance:

1. Teleroentgenographic and fluoroscopic evidence of aortic dilatation.
2. A tympanitic, bell-like, tambour accentuation of the second aortic sound.
3. A history of circulatory embarrassment.
4. Increased retromanubrial dulness.
5. Progressive cardiac failure.
6. Substernal pain.
7. Paroxysmal dyspnea.⁷

It is observed that, in those patients known to be syphilitic and with no evidence of mitral disease, these signs and symptoms are similar to those which Carter and Baker⁸ originally announced as the criteria for diagnosis of aortic regurgitation and aneurysm. This was subsequently reported by Moore, Danglade and Reisinger,⁹ who limited their study to uncomplicated syphilitic aortitis. The latter felt that the presence of three or more of these signs and symptoms in a syphilitic patient under 50 years of age, free from mitral disease and in the absence of hypertension, was strong evidence for the diagnosis of uncomplicated syphilitic aortitis and that the presence of any two of them renders the diagnosis probable.

It is hoped that as the result of these and other studies the attention of the physician will be called more closely to the importance of cardiovascular syphilis and to the necessity for its early detection. There were 270 syphilis cases in the group material which had signs and symptoms suggesting cardiovascular syphilitic involvement, and yet the stringency of present day criteria prevented their inclusion. It is felt that with careful history taking and with very careful physical examination, including x-ray studies, probably a considerable proportion of the patients thus far overlooked will in the future be detected in the early stage when the chances for the alleviation of their symptoms through treatment are more favorable.

MATERIAL STUDIED

Among 6,253 cases admitted with latent or late syphilis (principally central nervous system or cardiovascular), which were treated for six months or longer, there were 9.9 per cent who on admission manifested or subsequently developed cardiovascular syphilis. It was found that 4.9 per cent were cases of uncomplicated syphilitic aortitis, 4.1 per cent aortic regurgitation, 1.2 per cent aortitis with aneurysm, and 0.8 per cent myocarditis.

INFLUENCE OF COLOR AND SEX

This study confirmed the observations of others that the Negro is much more prone to develop cardiovascular syphilitic involvement than is the white patient. The percentage of Negro patients affected was three times as high as the white, and in the males this proportion was even more marked, being four times as great, while in the females the percentage was only a little over twice as high. The percentage of males was somewhat higher than that of the females in both the white and the Negro.

DURATION OF THE INFECTION TO DETECTION OF CARDIOVASCULAR SYPHILIS

There were twenty-three patients, or 7 per cent, in whom the cardiovascular syphilitic involvement was detected within five years after the syphilitic infection; in fact, in three instances uncomplicated syphilitic aortitis was diagnosed in the second year of infection. The highest percentage of cardiovascular syphilis was detected in the two decades ten to twenty years and twenty to thirty years after infection. In three patients the diagnosis was made forty years after infection.

BLOOD AND SPINAL FLUID SEROLOGIC REACTIONS

In those cases in which a serologic test of the blood was done within ten days before or after detection of cardiovascular syphilis, 79 per cent showed slight or definite positivity. Three of the five clinics used not only the Wassermann test but also one or more of the precipitation tests. One clinic used only the Kahn precipitation test, and the other clinic used several modifications of the Wassermann test. Lumbar punctures were not done on all the patients. In certain instances of advanced aneurysm or aortic regurgitation, clinical judgment precluded this procedure, but in 342 of the 642 patients on whom an examination of the spinal fluid was made 56 per cent showed definite abnormalities. The spinal fluid examination consisted of the Wassermann test, the globulin reaction, the colloidal gold or gum mastic test and the cell count.

CONCOMITANT SYPHILIS

Various writers in the past have mentioned the frequency of concomitant involvement of the central nervous system in connection with cardiovascular syphilis. The material of the Cooperative Clinical Group showed that in this series 278, or 43 per cent, of the patients also had syphilis of the central nervous system. In 9 per cent of the cases the syphilis of the central nervous system was asymptomatic. Therefore a physician managing a case of cardiovascular syphilis would do well to examine the patient carefully from the standpoint of concomitant involvement of the central nervous system, and, vice versa, the individual who has syphilis of the central nervous system should be studied very carefully from the standpoint of cardiovascular involve-

ment. What might be considered excellent preliminary treatment for syphilis of the central nervous system might well be far from suitable for concomitant cardiovascular syphilis. Other forms of concomitant syphilis occurred with a frequency of 4 per cent or less.

PROPHYLACTIC VALUE OF EARLY TREATMENT
IN PREVENTION OF CARDIOVASCULAR
SYPHILIS

The Cooperative Clinical Group material presents most encouraging data on the possible prevention of cardiovascular syphilis through treatment of early

TABLE 1.—*Prophylaxis of Cardiovascular Syphilis by Treatment of Early Syphilis*

Total.....	935	15	1.6	105	7	6.7

syphilis. In 3,641 cases in which treatment was administered during the early stages of the infection, less than 1 per cent have developed cardiovascular involvement to date. Only four patients, or one in a thousand, ever developed any of the graver forms of cardiovascular syphilis, and each of these had received less than twenty doses of an arsphenamine with interim heavy metal. In fact, in only two patients who were adequately and regularly treated during the early stages of syphilis was a definite diagnosis, even of uncomplicated syphilitic aortitis, ever made.

However, since 71 per cent of the cases of early syphilis have not been followed for a period of more than three years, there is a strong probability that in certain of these cases cardiovascular syphilis will be detected as the observation period is extended. In this series of treated early syphilis, 935 patients were followed for a period of from three to ten years, and 105 were followed for from ten to twenty years. Of the 935 patients fifteen, or 1.6 per cent, developed cardiovascular syphilis, and among the 105 patients, seven, or 6.7 per cent, developed cardiovascular syphilis. The detailed observations as related to treatment in the early stages of syphilis are shown in table 1. It is apparent from this table that the patient adequately and regularly treated for syphilis and followed for from three to twenty years after infection will be almost exempt from cardiovascular involvement. Moreover, there were no cases of aneurysm or of aortic regurgitation in such patients.

COMPARISON OF TREATED AND UNTREATED
EARLY SYPHILIS

The effectiveness of treatment as a preventive measure against late accidents in syphilis is most striking when these data are projected against the end results in cases of untreated syphilis. Bruusgaard's¹⁰ analysis

of Boeck's cases of purposely untreated early syphilis revealed 56 per cent of the cases followed for from three to twenty years after infection as symptom free, as compared with 93 per cent of such cases in the Cooperative Clinical material when they had received arsphenamine with interim heavy metal. Since only twenty years of the arsphenamine era has been passed through, it is impossible to prognosticate the relative effectiveness of good treatment as opposed to none in the decades twenty to thirty and thirty to forty years after infection, in which intervals Bruusgaard observed the highest percentage of patients with definite cardiovascular syphilis. However, the trend throughout the first and second decades appears most favorable for treatment.

TREATMENT PRIOR TO DETECTION OF
CARDIOVASCULAR INVOLVEMENT

A striking point that has been brought out by the Cooperative Clinical Group and emphasized also by others is the large percentage of patients with cardiovascular syphilis who have had little or no previous treatment. In the present study 69 per cent of the patients had had no treatment or only a little heavy metal prior to the detection of cardiovascular syphilis. An analysis of the individual groups indicates that the more advanced the involvement on admission the higher the percentage of untreated syphilis, as shown by the

fact that 62 per cent of the patients with uncomplicated syphilitic aortitis, 76 per cent of those with aortic regurgitation and 84 per cent in the group aortitis with aneurysm have been untreated previously. The further interesting observation was made that the amount of

10. Bruusgaard, E.: Ueber das Schicksal der nicht spezifisch behandelten Luetiker, Arch. f. Dermat. u. Syph. 157: 309, 1929.

treatment with arsphenamine and interim heavy metal prior to the detection of uncomplicated syphilitic aortitis was a definite factor in protecting the patient from progression to a graver heart involvement. Among the living patients eighteen progressed from uncomplicated syphilitic aortitis to a graver form; only two of these had received any modern antisiphilitic therapy prior to the detection of uncomplicated syphilitic aortitis. Among the eight dead patients who had progressed, only two had received as much as six doses of an arsenical with interim heavy metal prior to the detection of the uncomplicated syphilitic aortitis.

STATISTICAL CONTROLS FOR MEASURING EFFECTIVENESS OF TREATMENT

In order to meet the possible criticism that the patient's physical condition on admission was the factor that prevented those who died from receiving anti-syphilitic treatment rather than that the administered treatment had an important part in the continued life

Years of observation-treatment in patients with uncomplicated syphilitic aortitis, who were observed for at least one year.

of the individual, the following controls were created for the purpose of determining the effectiveness of treatment in the prolongation of life. Both the living and dead patients who were under treatment or observation for less than one year were eliminated. Then the years of life for the total patients in the two groups were determined and when it was found that proportionately as many of the living patients as those who died had been followed throughout each of the treatment-observation year periods it was concluded that the two groups had the same opportunity of receiving the indicated amounts of treatment and that therefore whatever prolongation of life had been accomplished was actually attributable to the varying amounts of treatment. The accompanying chart shows for cases of uncomplicated syphilitic aortitis the years of observation-treatment life completed by the indicated percentage of patients living as compared with those who have died.

The cases used in measuring prolongation of life through treatment in each of the varying stages of cardiovascular syphilis are limited to those followed for one year or more.

EFFECT OF TREATMENT AFTER DETECTION OF CARDIOVASCULAR SYPHILIS

Table 2 shows the effectiveness of treatment after cardiovascular syphilis had been diagnosed, expressed in terms of percentages of such patients who have died and the prolongation of life after the detection of cardiovascular syphilis.

The amounts of treatment after the detection of a syphilitic aortitis, aortic regurgitation or saccular aneurysm to the last observation or death are considered in four groups: those patients who received none or a small amount of arsphenamine and heavy metal; those who received little arsphenamine and much heavy metal; those who received little heavy metal and much arsphenamine, and the adequately treated group, those who received much of both drugs. Thirteen or more doses of arsphenamine with twenty injections or more of heavy metal or weeks of rubs was considered as much or adequate treatment; less than these amounts was considered as little or inadequate antisiphilitic treatment.

There were 267 patients with uncomplicated syphilitic aortitis, 16 per cent of whom had died and 84 per cent were still living on termination of the study. The percentage of deaths is higher among those who received inadequate treatment than among those who received an adequate amount of treatment after the detection of the uncomplicated syphilitic aortitis, 23 and 11 per cent respectively; however, the dead include patients dead from any cause. Among the forty-two patients who have died, those who had received an adequate amount of both drugs after the detection of uncomplicated syphilitic aortitis lived eighty-five months as compared with thirty-four months in those cases in which an inadequate amount was administered. In those cases in which an inadequate amount of either of the drugs was administered in combination with an adequate amount of the other, the life span was approximately fifty-six months. In those patients still living the effect of treatment on the prolongation of life cannot be expressed in definite terms, since one cannot foresee the ultimate life span of these individuals. However, there is a strong probability that the adequately treated patient will average a greater number of months of life than the inadequately treated. This statement is premised on the facts that proportionately twice as many inadequately treated patients have died as is true of the adequately treated, and also that more than one half of the total living patients have already received an adequate amount of therapy.

Similar data for the patients who are under treatment or observation for syphilitic aortic regurgitation also are given in table 2; 74 per cent of these patients were still living at the termination of the study and 26 per cent had died. The effectiveness of treatment in the prolongation of life can be observed in this more advanced form of syphilitic heart involvement. The average duration of life to the termination of the study when an inadequate amount of therapy was given was forty months, as compared with fifty-five months when an adequate amount of therapy was given. In the very small group of saccular aneurysms, fifty-nine in number, the average duration of life on termination of this study had been appreciably increased by adequate therapy, thirty-seven months to seventy-five months. The size of the group of aneurysms studied prohibits any definite statement on the end results of treatment but it appears

that there is some prolongation of life possible through adequate therapy begun after the detection of a saccular aneurysm.

PROGRESS OF UNCOMPLICATED SYPHILITIC AORTITIS IN SPITE OF TREATMENT

Of the total group of 267 cases of uncomplicated syphilitic aortitis followed for a year or more after detection of cardiovascular involvement, twenty-six progressed to more severe types of cardiovascular syphilis, 7 per cent to aortic regurgitation and 2 per cent to aortitis with saccular aneurysm. As was stated previously, only four of the twenty-six patients that progressed had received any treatment with an arsenical and interim heavy metal previous to the diagnosis of uncomplicated syphilitic aortitis. However, some of these subsequently had what would be considered good therapy, and in spite of this progressed, again confirming the advantage of preventive over curative treatment. In fact, eleven of the twenty-six progressing patients had more than eighteen doses of an arsenical with heavy metal after the detection of the uncomplicated syphilitic aortitis. It is also worth mentioning that none of these patients had ever had any treatment previous to the diagnosis. Five out of nineteen patients progressing to aortic regurgitation had received twenty-five or more arsenical injections. Indeed, it appears quite probable that certain of these cases may have progressed as the result of injudicious treatment.

SYMPTOMATIC RELIEF WHEN TREATMENT IS GIVEN AFTER DETECTION OF THE CARDIOVASCULAR INVOLVEMENT

What in the way of relief from symptoms can be expected if therapy is instituted for a syphilitic cardiovascular condition? In each of the stages of syphilitic cardiovascular involvement a higher percentage of patients experienced relief from their symptoms from thirteen or more doses of an arsphenamine with interim heavy metal than with less than this amount. The patients with uncomplicated syphilitic aortitis obtained relief in 67 per cent of the cases adequately treated as compared with 38 per cent inadequately treated. Among the patients with aortic regurgitation, relief was obtained in 60 per cent with adequate therapy as compared with 30 per cent inadequately treated. In the patients with saccular aneurysm, relief was obtained in 56 per cent of the cases adequately treated as compared with 30 per cent inadequately treated. Comparable forms of medical cardiac regimen had been used in all cases regardless of whether antisypilitic treatment was administered. These data indicate that adequate treatment not only prolongs life but also affords an alleviation of symptoms in a fair proportion of the cases.

THERAPEUTIC PARADOX

In view of the frequent concomitant presence of syphilis of the central nervous system and of cardiovascular syphilis, the physician may well use extreme care in instituting therapy. Any evidence of aortitis, aortic regurgitation or aneurysm would probably require a change in the type of therapy for central nervous system syphilis. Otherwise there might well ensue the sudden effect of a Herxheimer reaction or the slower effects of the "therapeutic paradox."

Wile¹¹ has called attention to the fact that certain patients with cardiovascular syphilis, if started imme-

diately on an arsenical drug, will show paradoxical improvement of symptoms at first, only later to have them aggravated. He feels that if an arsenical is used for beginning treatment in cardiovascular syphilis there may be too rapid healing of the inflammatory lesion, so that fibrosis, distortion and contraction of the tissues may result, and, for purposes of description, aortitis with mechanically intact valve leaflets may have so much fibrosis and contraction of the leaflets that the condition is changed into aortic regurgitation. Of course, the same theory applies not only to aortitis but also to aneurysm, to aortic regurgitation and even to syphilitic myocarditis.

TREATMENT OF CARDIOVASCULAR SYPHILIS

Since 78 per cent of the cases with severe cardiovascular syphilis had received little or no therapy for syphilis, the immediate need for better treatment in all early syphilis is recognized. The physician can and should prevent cardiovascular syphilis by thorough and continuous treatment of the early disease, giving at least twenty to thirty injections each of the arsenicals and heavy metal, preferably bismuth compounds.¹²

If cardiovascular syphilis is already present, the procedure to be followed will depend on the heart condition found. If the patient shows exertional dyspnea, edema or cyanosis, rest in bed for a month or more is desirable. If the presence of cardiac breakdown is revealed, digitalis in the form of the leaf, 0.2 Gm. a day, may be indicated. Patients with edema may be benefited by the diuretic¹³ action of the heavy metal salts. Certain patients will be unable to stand any arsenical and the physician must depend on mercury, bismuth and potassium iodide. The data, however, show that a large proportion of patients, if they are handled with care, will be much benefited by the cautious use of small doses of an arsenical, especially neoarsphenamine.

After a preliminary course of either mercury or bismuth compounds to prevent a "therapeutic paradox," the patient may then be started, very cautiously, on a dose of neoarsphenamine, 0.05 or 0.1 Gm., gradually worked up to a maximum dose of from 0.2 to 0.45 Gm., depending on body weight, a course of twelve treatments being given. The dose of 0.3 Gm. should rarely, if ever, be exceeded except in patients with uncomplicated syphilitic aortitis. It has been pointed out that better results were noted in cases of uncomplicated syphilitic aortitis when small rather than large doses of the arsenicals were used. In all cases any reaction, even a gastric upset, must be avoided in order to eliminate strain on the already overburdened myocardium. An arsenical for intramuscular use may well be employed in such cases. Between the succeeding courses of neoarsphenamine, an oil suspension of bismuth, e. g., sodium potassium bismuth tartrate 0.1 Gm. or an insoluble salt such as bismuth salicylate 0.1 Gm., may be used weekly for twelve doses. If the patient stands the therapy well, alternating courses of an arsenical drug or of a heavy metal should be kept up for at least two years, though our cases of uncomplicated syphilitic aortitis progressing to graver forms indicate that vigorous treatment must be avoided. Naturally, every case of cardiovascular syphilis should be kept under close

observation, treated according to symptomatology, and, if possible, a certain amount of treatment be given throughout life.

SUMMARY

1. It has been estimated that in the United States annually one-half million people with late syphilis seek treatment for the first time, about 50,000 of whom have a detectable cardiovascular syphilis.

2. Among 6,253 patients admitted with latent or late syphilis (principally central nervous system or cardiovascular) who were treated for six months or longer, there were 9.9 per cent who on admission manifested or subsequently developed cardiovascular syphilis. There were 4.9 per cent of cases of uncomplicated syphilitic aortitis, 4.1 per cent of aortic regurgitation, 1.2 per cent of aneurysm and 0.8 per cent of myocarditis.

3. Proportionately three times as many Negroes as white patients were affected, and among the males four times as many.

4. In 7 per cent of the patients with cardiovascular syphilis, involvement occurred within five years after the infection, but the largest group in ten to twenty years or twenty to thirty years after infection.

5. The blood serologic reaction was positive in 79 per cent of the cases. Concomitant syphilis of the central nervous system was found frequently. Among those patients on whom a spinal fluid examination was done, definite abnormalities were detected in 56 per cent.

6. In 3,641 cases in which treatment was administered in the early stages of syphilis, less than 1 per cent developed cardiovascular involvement. However, since 71 per cent have been followed for less than three years, there is a strong probability that in certain of these cases cardiovascular syphilis will be detected as the observation period is extended. Of 935 patients followed for from three to ten years fifteen, or 1.6 per cent, developed cardiovascular syphilis, and among 105 patients followed for from ten to twenty years, seven, or 6.7 per cent, developed cardiovascular syphilis.

7. In our series of patients followed for from three to twenty years, none developed aortic regurgitation or aneurysm provided they had been adequately and regularly treated during the early stages of syphilis.

8. Sixty-nine per cent of the entire Cooperative Clinical Group material had never had any specific treatment previous to detection of the cardiovascular syphilis. This was true of 62 per cent of the patients with uncomplicated syphilitic aortitis, 76 per cent of those with aortic regurgitation, and 84 per cent of those with aneurysms.

9. In determining the effectiveness of therapy after the detection of cardiovascular syphilis, the cases studied were limited to those under observation and treatment for one year or more. When thirteen or more injections of an arsenical with twenty or more injections of a heavy metal were given after the detection of the cardiovascular involvement, it appeared that not only was there some symptomatic relief of cardiovascular symptoms but also that there was a prolongation of life, the extent of which was dependent on the severity of cardiovascular involvement when anti-syphilitic treatment was begun.

10. The best treatment of cardiovascular syphilis is prophylaxis, i. e., at least twenty to thirty injections of an arsenical with interim heavy metal (bismuth) administered under the continuous system while the patient is in the early stages of syphilis.¹² Once the

patient has cardiovascular syphilis, in addition to symptomatic care, preferable treatment seems to consist of a preliminary course of intramuscular bismuth injections and potassium iodide by mouth, followed by the cautious use of arsenicals. Shock must be avoided at all times. If the therapy is well tolerated, alternating courses of the heavy metals and the arsenicals may be cautiously continued.

HYPERNEPHROMA ASSOCIATED WITH PREGNANCY

REPORT OF CASE

ERLE HENRIKSEN, M.D.

LOS ANGELES
AND

JOHN M. SPENCE JR., M.D.

BALTIMORE

The treatment of malignant tumors complicated by pregnancy is always a major therapeutic problem, especially if the patient refuses interruption of the pregnancy. The consensus of medical opinion strongly advocates the early sacrifice of the fetus when radiation therapy to either the pelvis or the abdomen is indicated, for experience has shown that therapeutic irradiation of the abdomen during gestation is extremely prejudicial to the future health of the fetus.

The apparent rarity of hypernephroma in gravid women is not remarkable if one bears in mind that this tumor usually occurs beyond the reproductive age. In our laboratory we do not designate as hypernephroma those tumors showing sex symptoms and invading the kidney from without, though these have frequently in the past been diagnosed both clinically and pathologically as hypernephromas. The new interpretation disagrees with Grawitz's original conception that tumors of the latter growth arise from cortical adrenal rests but interprets them as originating from the epithelium of the renal tubules. It is not within the scope of this report to elaborate on the origin and histology of hypernephroma. Suffice to say that it is characterized clinically by pain, visible or palpable mass in the flank, hematuria, loss of weight and symptoms referable to metastatic extension.

Success in the treatment of such a malignant growth, with or without the presence of an intra-uterine pregnancy, is dependant wholly on early diagnosis, followed by the immediate institution of proper therapy. Differential renal function tests with complete pyelographic studies as a rule are of prime importance in the diagnosis of this tumor even before the process is sufficiently advanced to produce pain or loss of weight.

The following report concerns the case of a white woman with a demonstrated hypernephroma, an intra-uterine pregnancy, and eclampsia superimposed on a chronic nephritis.

REPORT OF CASE

History.—E. G., a white woman, aged 40, weighing 220 pounds (100 Kg.), complained of "passing blood in the urine for six months." The family history was essentially negative. She was operated on five years ago for "gallbladder trouble." She had been married for twenty-four years and had four normal pregnancies, the last occurring fifteen years ago.

From the Gynecological Department of the Johns Hopkins Hospital and the Johns Hopkins University.
We are indebted to Dr. Guy L. Hunner and Dr. Charles D. Smith for assistance and to Miss Beverly Walton for the illustrations.
Owing to lack of space this article is abbreviated in *THE JOURNAL* by omission of the illustrations. The complete article appears in the authors' reprints.

Present Illness.—During the past six months she had experienced several attacks of painless hematuria, the urine being described as "bright red." Cystoscopic treatments resulted in the disappearance of the gross hematuria for a period of five months. However, two weeks prior to her admission to this service she had two attacks, each lasting one day, with a gradual clearing of the urine over a two to three day period. One week prior to her admission she experienced several attacks of sharp, nonradiating pain in the left flank, these being of about fifteen minutes' duration. She had lost 20 pounds (9 Kg.) during the present illness.

Examination.—The patient was large, obese and of foreign descent and did not appear ill. The temperature was 99.8 F.; blood pressure 145 systolic, 75 diastolic; hemoglobin 70 per cent. A catheterized specimen of urine contained innumerable red blood cells, with an occasional cast.

The abdomen was thick walled, and no tenderness was demonstrated on deep pressure over the kidneys. A vague mass was outlined in the left flank. The pelvic examination revealed the uterus enlarged to the size of about a three months' pregnancy, which agreed with her menstrual history. The patient admitted that she might be pregnant, though she thought this unlikely in view of the fifteen year period of sterility.

The two hour phenolsulfonphthalein kidney excretion test showed an output of 68 per cent. On cystoscopic examination the urethra and bladder were normal in appearance. A plain plate of the abdomen revealed a large irregular shadow replacing the left kidney; subsequent retrograde and secretory pyelograms showed a large irregular kidney on the left side, with a definitely distorted pelvis. The kidney function test on the left side was 10 per cent in thirty minutes. The right kidney was normal in outline, the pelvis was not distorted and the function was excellent.

Treatment.—Since the diagnosis of a hypernephroma involving the left kidney seemed quite certain, the patient was approached with an outline of the expected course of therapy, which included termination of the pregnancy. In spite of a full explanation of her condition and of the dangers to both the mother and the fetus, the patient emphatically refused any form of therapy that would not include every precaution to protect the life of the fetus. Five days after her admission to the service, deep radiation therapy to the left kidney region was instituted and within a period of thirty-five days a total of 6,600 roentgens was given.

The patient was then permitted to go home, with instructions to return at the end of six weeks. During the interim she was free from hematuria until the day before her readmission, at which time she experienced pain in the left flank followed by gross hematuria. On examination the mass, which had been easily outlined in the left flank on her previous admission, could not be palpated. The uterus was enlarged to the size of a six to seven months' pregnancy and fetal movements were present. Moderate pitting edema of the ankles had appeared. An ophthalmologic examination revealed an early retinal arteriosclerosis of the left eye. The blood pressure was now 160/100, the hemoglobin 70 per cent, the nonprotein nitrogen 26 mg. per hundred cubic centimeters. Retrograde and secretory pyelograms revealed no change in the normal right kidney. However, on the left side there was a marked change, the kidney shadow having decreased to nearly one-half the original size and being as a matter of fact smaller than the normal kidney on the opposite side (fig. 1).

Operation.—Under tribrom-ethanol-ether anesthesia the left kidney was removed through the transperitoneal approach. Some difficulty was encountered because of the obesity of the patient and the presence of the pregnant uterus. The kidney itself was remarkably free of adhesions and, after the pedicle was controlled, it was easily removed. The wound was closed in layers and supported with silver wire. The renal fossa was drained through a lumbar stab wound.

Postoperative Course.—The patient was in good condition on her return to the ward. The blood pressure remained around 150/110 during the entire time. The pitting edema of the ankles disappeared. The wound healed by first intention and the silver wires were removed on the thirteenth day. On the fifteenth day the kidney function test was 55 per cent for two hours. No evidence of metastasis was found following roentgenographic studies on the nineteenth day. Though we were

anxious to keep the patient under close surveillance until delivery, she was impatient to return home, so that she was discharged and referred to Dr. J. J. Jenkin and Dr. C. J. Carter of Farmington, W. Va., on the twenty-second day after operation.

The course at home was uneventful until the evening of the forty-eighth postoperative day, when there occurred a sudden attack of severe headache, closely followed by severe convulsions, and immediate surgical intervention was thought indicated. Under spinal anesthesia Dr. Carter successfully performed a classic cesarean section and delivered a normal appearing premature child of 1,540 Gm. The measurements of the child were normal in all respects. The mother was discharged as well on the fourteenth day. The child was kept in the incubator for the first two weeks and when discharged at the end of twenty-eight days weighed 2,155 Gm. To date (nine months) the baby has been in excellent health and has displayed no evidence of injury resulting from the roentgen therapy. Microcephaly, feeble-mindedness and skeletal defects are stressed in the literature; naturally feeble-mindedness will not be ruled out for some years. The mother has never fully regained her strength, though there is no evidence of recurrence or metastasis.

COMMENT

There are three special points of interest in this case, viz., the preoperative preparation, the operative approach and the effect of the irradiation on the child.

Waters, Lewis and Frontz¹ and Wharton² have recently advocated preoperative irradiation in tumors of the kidney and have presented a small series of patients showing that the size of the tumor mass is reduced and that the resultant postirradiation cellular destruction decreases the likelihood of recurrence. Histologic study of the removed tumor showed marked cellular changes with large areas of hyalinization and infarction; the entire picture was not that usually associated with the malignant hypernephroma, so that we feel justified in saying that the irradiation did actually alter the degree of malignancy. Under the supervision of Dr. C. D. Smith of the x-ray department, the following roentgen therapy was given within a period of thirty-five days: Three portals of entry were employed, each measuring 15 by 15 cm. The central ray was directed toward the left kidney at the level of the costal margin in the midaxillary line. Three fields, anterior, posterior and lateral, were used. One field was treated each day to deliver 220 roentgens (as measured at the skin) per treatment. Each field received ten treatments. The other factors were 190 peak kilovolts, 20 milliamperes, 50 cm. target-skin distance, and a filter of 2 mm. of copper plus 1 mm. of aluminum.

The cumulative effect at the central point of the tumor can be estimated at about 3,000 roentgens, or from 40 to 50 per cent of the skin dose. The inner curve as shown in figure 2 is 20 cm. from the skin and at this level the intensity is approximately 10 per cent. The outer (deepest) curve represents the deepest point of effective radiation.

In addition to the roentgen therapy, six pyelograms were taken in the latter part of the third month of pregnancy; two pyelograms were taken during the sixth month of pregnancy. At each exposure the patient received 240 milliamperes seconds at 30 inches target-film distance. The patient therefore, in the period between the latter part of the third month and the latter part of the sixth month of pregnancy, received 6,600 roentgens of high voltage therapy to the upper part of

2. Wharton, L. R.: Preoperative Irradiation of Massive Tumors of the Kidney, *Arch. Surg.* 30: 35 (Jan.) 1935.

the abdomen and 1,920 milliamperes seconds over the abdomen in the course of examination. No attempt is made to estimate the amount of radiation that reached the fetus and we believe that the radiation given in the manner described had no detrimental effect on the child.

Little or no change in the size of the left kidney mass was noticeable at the end of the radiation course, and the patient was sent home for a six weeks' rest. On her return at the end of the six weeks' period the changes illustrated in figure 1 were noted by both manual and pyelographic studies.

Because of the patient's obesity, the suspected malignancy of the tumor and the presence of a seven months intra-uterine pregnancy, the transperitoneal approach was selected. This type of tumor is made up of tissue notorious for its friability and for the ease with which it recurs following removal. There is also a marked tendency for such growths to extend into the renal pelvis and ureter and into the renal vein (fig. 3), as it did in this case. It was evident that the lumbar approach would necessitate undue and dangerous tension on the tumor mass during the ligation and severing of the pedicle. With the transperitoneal approach the pedicle was readily exposed and ligated without the tumor proper being touched. A large tumor mass could be outlined in the renal vein and extreme care was exercised so as not to break off any of the tumor thrombus. The period of time between the irradiation of the tumor and the operation was adequate, as the tumor mass had seemingly reached its maximum point of regression and no unusual bleeding or adhesions were encountered. Thus we feel that the decrease in the magnitude of the tumor and the apparent alteration of malignancy following radiation, with the ensuing facilitation of removal of the tumor mass, more than counterbalanced the disadvantage accruing from the increased growth of the uterus during the interim of treatment with possible hindrance of the operative procedure.

Miller, Corscaden and Harrar, who have recently reviewed the effects of radiation on the fetus, have concluded that irradiation during pregnancy for therapeutic purposes should be restricted to very clear and urgent indications; that it seems advisable to interrupt any pregnancy which has been subjected to therapeutic radiation, as it is generally admitted that serious radiation effects on the offspring will result in a high percentage of the cases. These effects are proportional to the amount of radiation and are more serious in early pregnancy, though the fetus may be seriously injured at any stage of development.

In reviewing the cases reported in the literature, we have been impressed by the lack of actual therapeutic data relative to the serious results of radiation on the health of the fetus in utero. We believe that this failure to include the technic of radiation employed limits the value of such reports. Thus with so few actual facts at hand we do not know the degree of risk of irradiating during pregnancy, if proper measures are taken to safeguard the fetus from the direct rays.

CONCLUSIONS

1. In the treatment of kidney tumors a diagnosis should be made as early as possible and proper therapy immediately instituted. Recognition of renal abnormality associated with neoplastic involvement is facilitated by complete urologic study. Obviously, early surgical

intervention offers the best prognosis, but when the clinical and pyelographic examinations reveal a more extensive tumor growth, preoperative irradiation should be resorted to. When used alone, the value of roentgen therapy is questionable.

2. The presence of hypernephroma in association with an intra-uterine pregnancy is exceedingly rare, but if the proper line of therapy is followed one is probably justified in permitting a continuation of the pregnancy.

3. In view of the notorious friability and transplantability of this type of tumor, the transperitoneal approach is indicated. By this method the pedicle is readily isolated and ligated, without tension or pressure on the tumor mass.

4. Because of the lack of complete data, there is no convincing evidence to warrant the routine interruption of pregnancy during therapeutic irradiation, unless the rays are placed directly over the fetus.

"PILOT ERROR" AND OXYGEN WANT

WITH A DESCRIPTION OF A NEW
OXYGEN FACE TENT

ALVAN L. BARACH, M.D.

NEW YORK

Although the number of accidents in commercial airplane travel has decreased since 1929, passenger fatalities have shown a marked rise. This is because more passengers are carried per airplane flight and therefore each major accident kills more people. Thus, while equaling their low record for accidents in 1936, the air lines made a new high record for deaths with a total of sixty-one, of which fifty-four were passengers. The cause of these accidents has been subjected to careful investigations both by the companies themselves and by governmental agencies. It has been said that pilot error enters into 90 per cent of all accidents, and in the most recent tabulation of the Department of Commerce this was considered the primary cause of sixteen out of twenty-seven accidents. The safety of the flying public would appear to be unduly dependent on a varying human personality if the analysis of the situation is correct and if no remedy for the situation can be found.

My evidence will be presented under the following on which the following conclusions may be reached:

1. Oxygen want is at times a factor in pilot error.
2. This factor (anoxia) is susceptible of immediate practicable remedy.
3. Compulsory oxygen inhalation should be adopted by commercial companies for pilots navigating at from 10,000 to 12,000 feet or over.
4. A comfortable, economical and efficient method for administering oxygen is now available; namely, an oxygen face tent originally developed for the treatment of anoxemia occurring in clinical disease.

My evidence will be presented under the following headings:

1. Oxygen want is capable of producing mental impairment and certain physiologic alterations at altitudes at which transcontinental commercial flying now takes place.

3. Miller, J. R.; Corscaden, J. A., and Harrar, J. A.: The Effects of Radiation on the Human Offspring. *Am. J. Obst. & Gynec.* 31: 518 (March) 1936. (Excellent bibliography.)

From the Department of Medicine, Columbia University College of Physicians and Surgeons, and the Presbyterian Hospital.

2. These disturbances in function of the human organism, induced by a reduced tension of oxygen in the tissues, are aggravated by certain forms of fatigue neurosis.

3. Pilots are apt to develop a characteristic form of fatigue psychoneurosis called aeroneurosis.

4. The combined effect of slight impairment of mental functioning induced by moderate anoxia and overt or latent aeroneurosis may become an influential factor in pilot error.

5. Safety in airplane travel may be increased by a recognition of these factors and a prompt application of suitable methods of preventing them.

The illness that develops at high altitudes, "mountain sickness" or "seroche," has long been known to be due to oxygen want. Many studies have been made on the physiologic and psychologic changes induced by exposure to reduced oxygen pressures at high altitudes and in chambers in which the pressure or concentration of oxygen has been artificially lowered.¹ The nature and severity of the symptoms produced at high altitudes are shown in the accompanying table, which has been condensed from that of Peters and Van Slyke.²

The more marked effects of oxygen want both mentally and physically have been studied at altitudes in the neighborhood of 15,000 feet. For the present purpose, however, it is important to point out that definite changes have been observed at altitudes of from 10,000 to 12,000 feet, an elevation frequently used in transcontinental flying. Thus tactual sensitivity was found decreased at 8,700 feet,³ increase in hand tremors at 8,400 feet,⁴ a decrease in reflex irritability at 8,400 feet,³ a diminution in performance in ergographic tests following rapid ascents from 9,500 to 12,000 feet,⁵ the onset of fatigue at 9,200 feet⁶ and impairment of neuromuscular efficiency at 12,000 feet.⁶

Of all the disturbances in the senses provoked by oxygen want, impairment in vision is the earliest to manifest itself. McComas⁷ reports that studies made by eye specialists of convergence and accommodation in thirty-five subjects during rebreathing tests revealed considerable loss of strength in the muscles of the eye. It was noted that at heights between 10,000 and 15,000 feet the subjects with slight convergence would see double. Experiments on aviators in the United States Air Force during rebreathing tests showed that diminished oxygen supply exaggerated to a marked degree any existing eye defect and unmasked a preexisting eye condition which would otherwise have escaped detection. In crash reports of aviators, accidents have been thought to be caused by such eye defects.⁸ Johnson

and Paschal⁹ believe that the disturbances attributed to vision impairment are more probably attentional than sensory. They have noted a depression of vision manifested not so much in the blurring of outlines as in a general darkening of the visual field and an intermittent cessation of all visual experiences, including that of darkness itself. Whatever the interpretation of the origin of the failing vision is, the importance of this sense in finding a landing needs no comment. Furthermore, the fact that a pilot has once been able to fly at 20,000 feet without conspicuous symptoms of anoxemia does not mean that he is a safe flier without oxygen at 10,000 feet. In fact, high flying appears to be followed by incapacity to tolerate even such moderate altitudes as 10,000 feet, and such fliers find their "ceiling" getting progressively lower.¹⁰ The importance of protect-

*Effects on Resting Normal Subjects of Acute Anoxia of Varying Intensity**

Degree of Anoxia	Oxygen Pressure of Inspired Air		Corresponding Altitude, Feet	Saturation of Arterial Blood with Oxygen	Symptoms
	Per Cent of an Atmosphere	Mm. Hg			
First degree: first obvious signs	10-12	120-90	8,000 to 16,000	89-85	Impaired mental concentration; muscular coordination disturbed; accelerated pulse and respiration
Second degree: precoma or post-coma; encountered either before unconsciousness or after recovery from short period of it	14-9	105-70	12,000 to 24,000	87-74	Judgment faulty; typical of alcoholic intoxication; hilarity or pugnacity; instability; muscular effort causes quick fatigue and may injure heart
Third degree: coma	10-6	70-45	24,000 to 35,000	74-33	Subject becomes unconscious; if in physical condition, coma is cerebral "with rigid, glassy eyed" unconsciousness almost instantly terminated by oxygen inhalation; if less fit, cardiac syncope occurs before cerebral; respiration reduced to gasps and stops; 6-8 minutes later heart stops

* Condensed from "Quantitative Clinical Chemistry" by J. P. Peters and D. D. Van Slyke, Baltimore, Williams & Wilkins Company, 1935, p. 588.

ing these fliers from premature loss of their usefulness by providing them with oxygen inhalation would appear a reasonable program in the light of these facts.

It must be admitted that the short duration of most psychologic tests of oxygen want limits somewhat the knowledge acquired from them. The clinical descriptions of mountain sickness are sufficiently abundant to provide incontrovertible evidence of the impairment in mental functioning at the high altitudes used in transcontinental aviation. Thus Heber,¹¹ in discussing the symptoms of the average European at Ladak Kashmir (11,500 feet), says: "The feeling of fitness on arrival soon gives way to a terrible weariness and restlessness, especially after a short day of mental work. The mental

deterioration is not as serious, however, as the change in temperament and all subjective functions. It is astonishing how the most decisive of men will slowly and insidiously lose the power of decision and become unwilling to bear responsibility." Barcroft¹² noted the increase in fatigability at Cerro de Pasco (14,200 feet) and the inevitable slowness and clumsiness at all work. In the clock test it took him twice as long to read the reverse face of the clock as it did at sea level. He

Fig. 1.—Large oxygen face tent.

remarked that any prolonged mental effort usually involved a degree of fatigue which necessitated a trip to the coast to prevent a "nervous breakdown."

Chemical reactions in the body due to oxygen deficiency include a lowered saturation of the arterial blood with oxygen, a decreased content of carbon dioxide, increased urinary acidity and an increase in nitrogen excretion, especially ammonia, in the urine. Loewy¹³ states that these changes may be observed in man at rest at altitudes as low as 2,450 meters, approximately 8,000 feet, and are more pronounced at altitudes of from 10,000 to 12,000 feet.

Several hours of moderate anoxia such as that produced by an altitude of from 10,000 to 12,000 feet, which may result in an arterial oxygen saturation of from 88 to 87 per cent, not only produces malaise and other symptoms of oxygen want, but these symptoms are apt to persist for some hours after return to normal oxygen conditions, as pointed out by Peters and Van Slyke,² presumably because of cumulative changes that take place in the cells before acclimatization can be accomplished. Recognition of this fact is of importance, since an aviator may be exposed to a reduced oxygen pressure at a certain period in a flight and the effects manifest themselves three or four hours later when traveling at low altitudes. Furthermore, in some individuals, acclimatization may not be attained for months or years; irritability and various sorts of malaise may be much more marked than at sea level, and prolonged residence at altitudes over 10,000 feet appears frequently to lead to premature cardiac failure.² I do not wish to emphasize the more severe symptoms that take place at altitudes of from 12,000 to 24,000 feet in which conspicuous interference with reason, judgment,

memory and control take place along with more pronounced cardiorespiratory symptoms ending in coma and collapse (third stage shown in the table) but to direct attention to the fact that mental impairment such as difficulty in concentrating and increased effort in attempting to concentrate occur at altitudes of from 10,000 to 12,000 feet to a varying degree depending on the individual. According to Barcroft,¹ the brain is the most vulnerable organ in altitude sickness. Although no opportunity has been had to investigate the pathologic effects of moderate degrees of oxygen want on the human brain, it is of interest to remember that cases of fatal anoxia, chiefly those due to carbon monoxide poisoning, have shown cerebral edema as their outstanding lesion, which may be attributable to the increase in capillary permeability observed experimentally by Landis.¹⁴

Since definite alterations in mental and physiologic behavior have been observed in normal individuals exposed to altitudes used in commercial flying, it is of special importance to realize that nervous states markedly augment the disturbing influence of oxygen want. During the past four years McFarland and I¹⁵ have made studies, psychologic as well as physiologic, on the effects of breathing varying oxygen mixtures on normal individuals, on subjects under the influence of alcohol and on patients with psychoneuroses. The similarity between drunkenness and acute oxygen want was apparent in many tested subjects. Furthermore, there was some evidence, both in the responses to psychologic tests and in the blood level of alcohol and lactic acid, that inhalation of high oxygen mixtures favorably influenced alcoholic intoxication in certain individuals.^{15a} The work of Palthe¹⁶ was only partially confirmed in this respect. That oxygen want conspicuously increased the symptoms of alcoholic intoxication was demonstrated in animals and in human subjects.^{15b}

Especially pertinent to our discussion are the results of breathing from 12 to 10 per cent oxygen mixtures in a group of patients suffering from psychoneuroses characterized by fatigue, neurasthenia and psychasthenia, when compared to normal subjects. Whereas very few of the control subjects showed more than impairment in judgment, memory and emotional control, and physiologic elevation of the pulse and blood pressure, a large percentage of the patients collapsed or showed marked deterioration in mental function.^{15c} Furthermore, undue fatigue such as that induced by keeping a subject

awake the night before the test resulted in responses to low oxygen similar to the patient with neurotic fatigue. Although the degree of oxygen want induced in these studies was definitely greater than that ordinarily employed in transcontinental aviation, the results obtained clearly revealed an increasing inability of the individual suffering from fatigue psychoneurosis to handle oxygen want as compared to the normal person.

The argument leads now to the fact that a characteristic form of psychoneurosis develops among air pilots.

Fig. 3.—Oxygen concentrations in the large (solid line) and small (broken line) oxygen face tent at varying oxygen flows.

During the World War there was an enormous percentage of air pilots of all countries invalidated because of functional nervous disorders. Anderson,¹⁷ because these conditions developed as the result of flying, coined the term "aeroneurosis"; other authors referred to the syndrome under descriptive terms such as "aerosthenia" and "chronic fatigue."¹⁸ Armstrong¹⁹ defined aeroneurosis as a chronic functional nervous disorder occurring in aviators characterized by fatigue of the higher voluntary mental centers, insomnia, emotional instability, gastric distress, nervous irritability and increased motor activity. Although anoxemia is listed as a possible physical factor, the pathogenesis was regarded as essentially concerned with the profound and long continued emotional stresses encountered in this type of occupation. Armstrong (1936) concludes his study of American pilots as follows: "From a study of the functional nervous disorders occurring in 163 unselected airplane pilots over a period of three years, it is concluded that: Of the group studied, 11.04 per cent suffered from a special form of the psychoneuroses, which affect 3 per cent of those in the age group 22-29, 50 per cent of those in the age group 30-39, and 57 per cent of those in the age group 40-49."¹⁹

In the gassed soldiers in the war a neurosis developed described as a "disordered action of the heart." Barcroft, Hunt and Dufton²⁰ regarded this as due to chronic oxygen want and obtained definitely beneficial results by continuous oxygen administration in chambers. Haldane²¹ observed that patients returned from

the World War with a diagnosis of "soldier's heart" or "neurasthenia" suffered from rapid, shallow breathing, a sense of impending suffocation, general nervous irritability and shortness of breath on exertion. He suggested that military neurasthenia was a more lasting form of fatigue due to oxygen want. Schneider²² observed that "stale or fatigued pilots" were frequently rapid, shallow breathers and more sensitive to oxygen deprivation. The implication that anoxia may be concerned in the pathophysiology of neurosis is strengthened by the observations of Hess,²³ who believed that oxygen exchange between the alveolar air and the arterial blood is inhibited by vagus action, and by Kroetz,²⁴ who reported that the arterial oxygen saturation of neurotic patients showing vasomotor instability might suddenly fall from the normal level of 95 per cent or over to 85 per cent as a result of emotional stress. Both clinical and experimental results support a tentative hypothesis that repeated exposure to oxygen want at high altitudes may be a factor in the development of nervous disorders in pilots.²⁵

Since fatigue and psychoneurotic states augment the harmful effects of anoxia mentally as well as physically, and since these states are especially liable to develop in aviators, it seems reasonable to provide pilots with the only safeguard known to combat anoxemia; namely, continuous oxygen inhalation during flights at altitudes between 10,000 and 12,000 feet or higher.

I shall now describe a simple oxygen face tent which appears to have advantages over other forms of portable apparatus. A box mask enclosing the face and neck has been described by Campbell.²⁶ It consists of an aluminum or cardboard frame to which linen is attached. The latter may be moistened with water and the evaporation of this tends to cool the apparatus. A similar device has been developed by Taylor²⁷ except that oxygen and air are first passed through a refrigerating cabinet. A manufacturer²⁸ has advertised an

Fig. 4.—Oxygen (broken line) and carbon dioxide (solid line) concentrations in the oxygen face tent at varying oxygen flows.

inhaler which covers the nose and mouth. The oxygen face tents shown in the accompanying illustrations are made of light, transparent plastocoele. They fit over

the bridge of the nose and may easily be molded to the conformation of the patient's face. They are attached to the head either by ear pieces or by an elastic band. Oxygen is admitted through perforated rubber tubing placed horizontally at the upper part of the mask. A shelf made of the same material extending downward from the top of the face allows oxygen to collect during expiration and tends to prevent leaks at the top of the mask; it also directs the patient's expired air downward and out of the tent and thus prevents warm air from being reflected directly backward on the patient's face. Provided 4 or more liters a minute of oxygen is continuously administered, additional cooling is generally not necessary. The oxygen is admitted dry without passing through a water bottle, since sufficient moisture remains within the tent from the patient's previously exhaled air to provide a comfortable relative humidity.

In figures 3 and 4 the oxygen and carbon dioxide concentrations in the inspired air at varying oxygen flows are shown for a small and a large face tent. It will be observed that the oxygen concentration in the small face tent was found to be 36 per cent at 4 liters a minute, 42 per cent at 6 liters and 47 per cent at 8 liters; in the large face tent the oxygen concentration was 43 per cent at 4 liters, 52 per cent at 6 liters and 62 per cent at 8 liters a minute. The increased volume in the larger tent allows for a greater storage of oxygen admitted from the tank during expiration. The carbon dioxide concentration in the inspired air is seen to be 2 per cent or under when 4 or more liters a minute is administered. In the treatment of anoxemia in clinical medicine this is the minimum flow at which a face tent should be used; at high altitudes 3 liters a minute may be employed, since slightly higher carbon dioxide concentrations may be advantageous under these circumstances. The foregoing measurements were obtained by placing a large tube in the oral pharynx with the mouth closed during administration of oxygen. Samples were taken during inspiration. Variations of approximately plus or minus 1.5 per cent were found, depending on the volume and character of the pulmonary ventilation. For clinical purposes the large face tent with an oxygen flow of from 6 to 8 liters a minute is generally desirable, since this provides an effective concentration of oxygen. When used to combat the anoxemia of high altitudes, from 3 to 4 liters a minute (with the small face tent) will produce a concentration of oxygen above 21 per cent in the inspired air at from 10,000 to 12,000 feet respectively, and from 6 to 8 liters a minute will provide an oxygen concentration approximately that of the atmosphere, or higher, at from 16,000 to 25,000 feet.²⁹ The concentration of oxygen required may be calculated readily by relating the altitude to the barometric pressure and then calculating the percentage of increase in oxygen concentration required to overcome the percentage of decrease in the barometric pressure from 760 mm. of mercury.

Since this communication is particularly concerned with oxygen inhalation for pilots operating in transcontinental flights between 10,000 and 12,000 feet, it is of value to compute the weight of the additional equipment necessary. A 110 cubic foot tank of oxygen contains 3,000 liters. At a flow of 4 liters a minute, which will provide an oxygen concentration slightly higher

than that of atmospheric air at 12,000 feet, a single tank will last twelve and one-half hours for one pilot or approximately six hours for two pilots. At a flow of 3 liters a minute, which would provide an oxygen concentration approximately that of the atmosphere, a single tank would provide two pilots with oxygen for more than eight hours. Higher oxygen concentrations would be provided by the larger, somewhat more cumbersome tent. The tank weighs 94 pounds (43 Kg.), the oxygen regulator, tubing and face tent 5 pounds (2,268 Gm.); the total increase in weight, therefore, is less than 100 pounds (45 Kg.). The cost of both the oxygen and the apparatus is nominal.

This oxygen face tent provides, in my experience, more comfort than a nasal or oropharyngeal catheter or nasal inhaler. It does not interfere with vision. It can be easily removed and reapplied, with an almost immediate building up of the oxygen concentration desired. The face tent, however, does not provide a cool, dry atmosphere, although it has been found comfortable for hospital patients. Its advantages are its simplicity, inexpensiveness, comfort and effectiveness. It is my belief that an apparatus of this kind is practicable for pilots. The oxygen released into the cabin of the pilot would not raise the oxygen concentration to an appreciable extent, since leaks under the doorway would prevent any undue accumulation of oxygen.

In a transcontinental airplane flight which I made at from 10,000 to 12,000 feet, a pilot who consulted me on a method of overcoming the sleepiness from which he suffered revealed the fact that he did not take oxygen and made the statement that he did not need it. It should be borne in mind that the effects of oxygen want are insidious and that overconfidence is as characteristic as it is in alcoholic intoxication. The responsibility for inhalation of oxygen should not, in my opinion, be left with the pilot but should be decided by the administrative department of the company. In this way the flying public would be more apt to be protected against the factor of pilot error due to oxygen want or previously experienced oxygen want. In addition, it is entirely possible that the aviator himself not only would function better because of oxygen inhalation but might be partially protected against the development of the psychoneurotic state known as "aeroneurosis," at least as far as it might be caused by repeated exposure to anoxemia.

SUMMARY

Oxygen want is capable of producing mental impairment and physiologic alterations at altitudes of from 10,000 to 12,000 feet, at which much transcontinental flying takes place at the present time. Fatigue and psychoneurotic states seriously aggravate the dangerous effects of oxygen want.

Pilots are apt to develop a characteristic form of psychoneurosis called "aeroneurosis" in which fatigue is a prominent symptom. The combined effect of impairment of mental functioning and overt or latent aeroneurosis may become an influential factor in pilot error. Safety in airplane travel may be increased by a recognition of these factors and by the adoption of compulsory oxygen inhalation for pilots flying at altitudes at or above 10,000 to 12,000 feet.

The simple oxygen face tent described is practicable, efficient and comfortable. It appears to be a suitable method of oxygen inhalation for pilots, as well as being applicable to the treatment of oxygen want in clinical disease.

893 Park Avenue.

29. More circulation of air in the face tent may be obtained by connecting a simple bunsen burner type of injector to the regulator, which then delivers approximately 75 per cent oxygen and 25 per cent nitrogen. The apparatus may be made locally or secured from the Oxygen Therapy Service Company, 247 East Fifty-Sixth Street, New York.

**Clinical Notes, Suggestions and
New Instruments**

**A TUBE FOR USE IN THE POSTOPERATIVE CARE
OF GASTRO-ENTEROSTOMY CASES**

W. OSLER ABBOTT, M.D.
Instructor in Medicine and F. M. Kirby Fellow in Surgical Physiology,
University of Pennsylvania School of Medicine
AND
ARTHUR J. RAWSON, M.E.
Associate in Medical Physics
PHILADELPHIA

Stimulated by a suggestion from Dr. I. S. Ravdin we have devised, for routine use during the first few days after gastric operations, a tube which makes possible alternate jejunal feeding as advised by Andresen¹ and aspiration of the stomach

Fig. 1.—Longitudinal and transverse sections of the valves: Of the various patterns used, this is probably the best. The gastric or inlet valve on the left is approximately the diameter of the tube, in contrast to the larger outlet valve on the right. This enables the surgeon to locate the end of the tube more certainly. The actual dimensions of the valves are varied in relation to the size of the tube on which they are to be mounted.

contents as advocated by Wangensteen and Payne.² Our first experience in attempting to combine these two principles in one apparatus was in a case requiring at the same time a gastro-jejunoscopy and a gastrostomy. A double-lumened rubber tube³ was passed through the gastrostomy, one lumen for communication with the stomach, the other for communication with the jejunum. Though this procedure achieved its objectives it was, of course, unpractical since rarely are both operations required. Furthermore a double-lumened tube of sufficiently small size to pass through the nose could not have lumens large enough freely to transmit mucoid or bloody gastric contents. Therefore we have abandoned the use of a double-lumened tube and have devised two silver valves (fig. 1), which may be mounted on standard single-lumened tubes of size 12 to 16 F., as these will lie comfortably in the average nose. The proximal valve in the stomach allows fluid to enter but not to leave the tube. The distal valve in the jejunum 30 cm. beyond allows fluid to leave but not to enter the tube. The valves themselves may be made small enough to pass through the nose, but, because it is easier for the surgeon to find the end of the tube in the stomach by palpation if the distal valve is larger, we either attach a "duodenal bucket" to the end of the tube beyond the outlet valves or make the terminal valve of a large size. The tube may then be passed as follows:

The tube is swallowed before operation. A small catheter is passed in through the nose and out at the mouth. The proximal end of the tube is attached to the catheter and drawn in a

retrograde fashion back through the mouth and out at the nose, leaving the patient's mouth unencumbered. The gastro-enterostomy is performed as usual and on the completion of the anastomosis the tip of the tube is located by palpation and slipped through the stoma down into the jejunum till the proximal valve is felt leaving the stomach. The anesthetist then withdraws the tube till this valve lies well within the

Postoperative Fluid Balance

* A liquid diet each 100 cc. of which contains 5 Gm. of protein, 9.5 Gm. of fat and 10.8 Gm. of carbohydrate, totaling 148.7 calories. This flowed somewhat too slowly, reducing the fluid intake for the third day.

stomach and applies adhesive tape to hold the tube in place. When the patient has been returned to the ward, siphon suction is applied to keep the stomach empty. About six hours later a connection is attached to a three-way stopcock joining the tube to the suction apparatus and water is given directly into the jejunum. Later, as occasion warrants, solutions of salt,

V. and none has regurgitated back to the stomach from O. V.

dextrose, protein, vitamins or other nutritive preparations are similarly injected. Suction is continued throughout the intervals between feedings. The following case exemplifies the procedure:

D. N., a man, aged 55, had experienced recurrent attacks of duodenal ulcer symptoms from the age of 40. Five months before admission to the ward, evidence of beginning cicatricial stenosis of the pylorus first appeared, a condition that finally reached a point necessitating operation. After preparation in the medical wards he was transferred to the service of Dr. E. L. Eliason. Prior to operation the tube was passed as

described. Under ether anesthesia an anticollic posterior gastro-jejunosomy was performed. The end of the tube was placed in the jejunum, and the patient was returned to the ward. The fluid balance of the first four days is summarized in the accompanying table. More fluid could have been given had it seemed necessary, as the volume introduced was not limited by the occurrence of symptoms.

On the fourth postoperative day two roentgenograms were made, the second of which was taken after the injection of 40 cc. of a thin barium sulfate suspension (fig. 2). It is apparent that the barium neither leaked into the stomach through the upper valve nor regurgitated into the stomach from the jejunum, though immediately after operation regurgitation probably occurred repeatedly, judging by the character of the drainage flow. The tube was then withdrawn without resistance.

It is unlikely that such a tube is detrimental to the suture line. In one patient in whom an 18 F. tube traversed the stoma for the thirteen days between the making of a gastro-enterostomy and death, the necropsy revealed no trace of pressure necrosis or inflammation of the mucous membrane. This case is important in that the cachexia of the patient was extreme. The operation was necessitated by failure of gastric emptying over a period of nearly a month during which time nutrition was maintained almost exclusively by parenteral routes. The patient was desperately ill much of this time from the effects of ulcerative colitis and a fecal fistula following a previous partial colectomy, so that were the presence of a tube likely to jeopardize healing it should have been apparent in this instance.

We feel therefore that the use of a tube with valves for the filling of the jejunum and the emptying of the stomach is both a practical and a helpful measure in the postoperative care of patients in whom an anastomosis between the stomach and the intestine has been formed.

133 South Thirty-Sixth Street.

A COMBINATION RESUSCITATOR AND INCUBATOR FOR NEW-BORN INFANTS

A. ROBERT BAUER, M.D., DETROIT

The apparatus herein described was built in July 1931 to meet in a practical way the well established needs of the premature or the full term new-born infant suffering from respiratory or circulatory embarrassment; namely, (1) carbon dioxide-oxygen mixture¹ for stimulation of the respiratory centers, (2) oxygen² to combat anoxemia, (3) external heat to maintain body temperature, (4) easy accessibility to provide feeding and nursing care with a minimum of handling and without removing the baby from the atmosphere of oxygen, and (5) full visibility to insure careful watching. Continuous use of the apparatus in the nursery of the Henry Ford Hospital for five years has proved its value in treating cases of asphyxia neonatorum, intracranial hemorrhage, atelectasis, congenital heart disease, blood dyscrasias, excessive mucus or any other condition that might cause cyanosis or anoxemia. While statistics to prove it are difficult to gather, it is the opinion of those who have used the apparatus that it has saved several lives and has prolonged life in others long enough for other therapeutic measures to be successfully instituted.

The apparatus consists of a carriage, a large size tank of carbon dioxide-oxygen and one of oxygen (both having suitable reducing valves), a glass cabinet, and a thermostatically controlled electric hot water heating and humidifying system. The heating system gave the most trouble. We found that it was almost impossible to maintain safely a steady, desirable temperature with the available appliances, and so we constructed a miniature hot water system similar to the systems used in heating houses. This, controlled by a thermostat, will give a

temperature variation of less than 5 degrees F. The humidity is supplied by the expansion chamber of the heating system and is controlled by adjusting a slide on the top of the chamber.

The operation of the apparatus is simple and requires only reasonable watching. It is kept in the premature nursery always ready for use. The heating unit should be turned on as soon as it is seen that a baby will need treatment, so that the cabinet will be preheated. It was found that by setting the thermostat at 85 F. a temperature varying between 85 and 90 was obtained. This was satisfactory for most cases. As a rule, babies requiring treatment needed stimulation as well as oxygen; therefore they were started on the carbon dioxide-oxygen mixture. This is introduced into the cabinet at the rate of 10 liters per minute for two or three minutes to get a rapid concentration. After this the rate of flow is cut to 3 liters per minute, which is enough to maintain the desired concentration. The carbon dioxide-oxygen mixture is continued until respirations are full and even, and then it is stopped and oxygen is run in at the rate of 3 liters per minute. From this point on, the carbon dioxide-oxygen mixture is used instead of oxygen whenever the baby needs further stimulation, and it is used as

Combination resuscitator and incubator for new-born infants.

long as necessary. On general principles, the carbon dioxide-oxygen mixture was given for ten minutes out of each hour and oxygen for the other fifty. This was found to meet the requirements of most babies. Apropos of the controversy incident to the variance in the points of view of Henderson and Eastman, it was the clinical observation that in the average case the carbon dioxide-oxygen mixture was followed by an increase in the depth and rate of respirations not seen with oxygen. The amount of continuous treatment varies for different cases from one-half hour up to two days, the treatment being stopped when the baby breathes well and retains a good color outside the cabinet.

The other two features, accessibility and visibility, need no comment other than to say that the very ill patients are cared for inside the cabinet, as they become cyanotic when removed for even a very short time. Those not so ill may be kept out for varying periods of time depending on their condition.

THYMOL THERAPY IN ACTINOMYCOSIS

HAROLD B. MYERS, M.D., PORTLAND, ORE.

A few of the volatile oils, namely, thymol, carvacrol, mustard, cinnamon and clove, have been shown¹ to possess fungicidal properties of considerable merit. Thymol and its liquid isomer carvacrol are the only members of this group of fungicidal volatile oils possessing the power of destroying *Actinomyces* quickly, when in aqueous solution. Thymol and carvacrol each kill *Actinomyces* in forty-five seconds in 1:1,000 aqueous solution. This marked toxicity toward *Actinomyces* suggests the possibility of therapeutic value.

An opportunity to test the therapeutic merit of thymol in human actinomycosis presented itself in 1924. An abbreviated case report follows:

J. N., a white man, aged 59, a blacksmith, habitually chewed straw. He slept on straw while recently employed on a ranch. He was seen Aug. 10, 1924, because of a mass "the size of a pigeon's egg" at the juncture of the right zygoma with the mandible. The teeth of both jaws on the right side had been removed. Physical examination revealed nothing of noteworthy interest other than as stated. A diagnosis of osteosarcoma was made on this date and high voltage x-ray therapy was given. The lesion increased in size, fluctuation being evident September 15. It was incised and pus was sent to the laboratory, staphylococci being reported. The lesion continued to increase in size, reaching from the level of the outer canthus to 5 cm. below the ramus of the mandible on December 24, when a fluctuating extension was incised and *Actinomyces* was identified on microscopic examination. Potassium iodide was given in rapidly increasing dosage, reaching 16 Gm. (250 grains) a day. The lesion continued to increase during fifty-eight days of iodide administration. Iodide therapy was then discontinued and thymol therapy instituted in a dose of 1 Gm. by mouth, twice a week. Seventeen days following the beginning of thymol therapy, the record states, the swelling had almost disappeared and the patient could open his mouth a short ways. There being no complaint from the use of thymol, the dose was increased to 1.5 Gm. March 21, 1925. The record states that the patient was apparently cured and was discharged April 25. The patient agreed to return to the outpatient clinic in the event any suggestion of recurrence developed, but he did not return.

The results in this case encouraged the further trial of thymol in actinomycosis, recorded in briefly abstracted form as follows:

CASE 2.—A. S., a white man, aged 45, a farmer, seen in April 1925, had a discharging abscess under the left mandible. He had first noticed it two months previously, following infection of a tooth. The lesion increased in size, the patient being presented three weeks later for diagnosis at a clinic, *Actinomyces* being identified under the microscope. Thymol was prescribed in capsules, 1.5 Gm. once a day, on alternate days. According to his physician's record he "recovered completely in about one month's time and remained without recurrence."

No further patients with actinomycosis were observed until 1934.

CASE 3.—W. G., a white man, aged 58, a farmer, seen Feb. 13, 1934, had an indurated mass measuring 6 by 6 cm. in the right groin. He first noticed it January 4 and thought at first it was a hernia. The mass was covered by skin pigmented reddish brown. It was firm and not particularly sensitive to pressure. The lesion was not diagnosed, and on March 8, the mass being 8 by 10 cm., an area of localized fluctuation was incised and *Actinomyces* was identified under the microscope. Thymol 10 per cent in olive oil was injected into the open lesion and thymol 1.5 Gm. once a day, on alternating days, prescribed. The patient refused to take the capsules following the fifth dose, because of gastric irritation. The local therapy was given at increasing intervals of days, owing to the breakdown and discharge of the granulomatous mass. The lesion became more sensitive as the mass disintegrated. April 9 the patient was allowed up from bed. The local lesion showed rapid improvement. An

attempt to resume systemic thymol therapy was made but the patient refused to swallow the capsules because of the gastric irritation produced. May 8 he complained of pain in the back. A roentgenogram indicated an area of consolidation in the left lung with extensive adhesions. No fluid was visible. The right lung was clear. Further roentgenograms at frequent intervals showed increasing involvement of the left lung. Repeated cultures of fluid obtained by thoracentesis and of sputum failed to yield a growth of *Actinomyces*. The lesion in the right groin healed. The patient died October 10 and necropsy showed an actinomycotic empyema and abscess of the left lung; the lesion in the right groin was healed and showed no evidence of active infection.

CASE 4.—E. M., a man, aged 38, a Filipino, had a swelling of the right jaw, Aug. 7, 1934. *Actinomyces* was identified from curetted material obtained from the incised area October 11. Thymol crystals in capsules were given by mouth once each day in a dosage of 1.5 Gm. for a period of twenty days. Thymol 10 per cent in olive oil was injected into the sinus tract (holding approximately 2 cc.) once each day for sixteen days. The patient was discharged at the end of this period as "clinically cured." He was kept under observation in the outpatient clinic with no evidence of recurrence over several months, when he was finally released.

CASE 5.—C. G., a white man, aged 36, was admitted to the hospital in June 1934 with the differential diagnosis of "subpectoral abscess" or "osteosarcoma." July 22 a biopsy revealed *Actinomyces*. X-ray examination showed pulmonary involvement. Iodide 3.3 Gm. (50 grains) was given daily. The patient was intolerant of larger doses of iodide. Morphine was administered to relieve pain. Serial roentgenograms indicated increasing involvement of the pulmonary lesion. Thymol therapy was begun October 12 with dose of 2 Gm. in capsules, by mouth, once a day; olive oil solution of thymol 10 per cent (later increased to 15 and 25 per cent) was injected into the sinus tracts. Marked clinical improvement was shown. X-ray comparison showed a marked decrease in pulmonary infiltration. There was gain in weight to 152 pounds (69 Kg.). The weight on admission was 140 pounds (63.5 Kg.) with subsequent loss. The discharge from the sinus tracts, though diminished, has not altogether ceased. Roentgenograms of the chest on Aug. 17 and Oct. 9, 1935, showed no evidence of further extension of the lesion in the lungs.

CASE 6.—M. L., a white woman, aged 40, a housewife on a farm, first noticed inflammation of the left shoulder March 21, 1936. Three days later it was diagnosed "erysipelas" and an ointment was prescribed for local application. The lesion rapidly extended toward the neck, the left breast and down the left arm. *Actinomyces* was identified under the microscope from pus obtained from a sinus April 18. Thymol therapy was begun April 21 with oral dose of 2 Gm. (30 grains) once a day and a 20 per cent solution of thymol in olive oil was injected into the sinus. The thymol dosage was decreased to 1 Gm. once a day June 21 and was discontinued August 24. Surgical repair of extensive sinus tracts over the pectoral region and shoulder was carried out September 10, with subsequent healing and no further evidence of actinomycotic infection.

SUMMARY

Five patients with actinomycotic infection were treated with thymol locally and systemically, each one recovering. Patient 3 refused to take thymol internally and died of visceral actinomycosis, though the original lesion healed under local therapy. Patient 5 still has a discharge from the sinus tracts. A similar discharge stopped in patient 6 after surgical repair at the completion of thymol therapy. From the experience obtained with the patients whose records have been briefly abstracted, thymol therapy in actinomycosis seems worthy of further clinical trial. It should be applied locally whenever possible in olive oil solution, from 10 to 20 per cent in strength. Systemic therapy with thymol is advisable in attacking the infection and preventing its spread to other parts of the body. Thymol may be given in crystal form in capsules, one dose a day in order to obtain a peak load in circulation. It should be given on an empty stomach to avoid retention and irritation of the stomach and, furthermore, to speed absorption and obtain as high a concentration in circulation as possible. A glass of milk may be given to minimize gastric irritation. Sinus tracts may require surgical repair following the destruction of the actinomycotic infection.

Dr. Myers died March 16, 1937.

CHRONIC DISEASE AND GROSS IMPAIRMENTS IN A NORTHERN INDUSTRIAL COMMUNITY

GEORGE ST. J. PERROTT

AND

DOROTHY F. HOLLAND

Principal Statistician, and Associate Statistician, Respectively,
United States Public Health Service

WASHINGTON, D. C.

The increasing importance of the problem of chronic disease challenges the best efforts of the medical and public health professions toward a broad program of control. Its social consequences masked in the larger problems of unemployment and dependency among young and old, chronic disease presses on the national scene today as an essential although undeveloped aspect of the broader program of social security. An effective program of control demands cooperation in broad policies and an appropriate division of labor:

Chart 1.—Prevalence of certain chronic diseases and gross impairments. Sole, primary or contributory diagnosis; exclusive of deaths. Orthopedic cases are exclusive of impairments of fingers and toes.

in the field of medicine, continued research on the etiology of certain chronic diseases and experimentation with promising therapeutic procedures; in the field of public health, the prevention of predisposing acute diseases, community education to promote early diagnosis, and the provision of adequate facilities for the care of chronic cases in the low income groups. From the public health standpoint, the scope of a coordinated program must be determined with reference to exact knowledge of the magnitude of the problem in various local areas. With the purpose of extending this essential basic information, which now exists only for limited areas and special groups, the United States Public Health Service in 1935 conceived the plan for a comprehensive health survey¹ designed to define the problem of chronic disease on a national scale.

The leading position of the chronic diseases as causes of death is familiar to all observers of mortality trends. A striking indication of the change in their relative importance is contained in the mortality

experience of the state of Massachusetts during the past fifty years.² In 1880 and 1900 a selected group of the major chronic diseases³ accounted for approximately one third of all deaths; in 1930 deaths due to these causes represented approximately two thirds of the total deaths.⁴ On the other hand, a group of typical acute diseases⁵ which, in 1880 and 1900, ranked in importance with the chronic group as causes of death, in 1930 caused only one death for every five resulting from the major chronic diseases. In the country as a whole in 1933 the cardiovascular-renal diseases alone caused 41 per cent of all deaths of persons from 45 to 64 years of age, and 58 per cent of the deaths at ages 65 and over.⁶ Further extension of the evidence from our mortality statistics is unnecessary, since its implications are familiar even to the layman.

Less widely recognized, however, are the characteristics of chronic illness which lead to its predominance among the public health problems of the present. The cost and complexity of treatment required by the major chronic diseases is known to both patient and physician. The social and economic disorganization resulting from chronic illness of long duration extends the problem beyond the stricken individual to the family, with ultimate transfer of responsibility to the community when the family is unable to absorb the economic burden without public assistance. We find, however, that public assumption of responsibility for the chronic sick is limited chiefly to the crippled, tuberculous, syphilitic and mentally diseased, facilities for the care of which are by no means uniformly adequate. With these exceptions, the control of chronic disease is rejected from the accepted scope of public health activity. Notwithstanding the efforts of certain pioneers in public health theory, both state and local health department practice shows a general lack of development in this field, and it is significant that the first community program for the care of the chronic sick represents the result of the joint effort of a medical specialist in the treatment of chronic disease and a local social agency.⁶

The United States Public Health Service looks to the completed results of its health survey⁷ of some 3,000,000 persons in ninety-two representative urban communities⁸ as a contribution toward a factual basis from which such a community program may be evolved. Furthermore, the analysis of the survey data will supplement existing knowledge of the health requirements of the dependent groups included within the scope of the present social security program. The definition

2. Special tabulation of figures from the Thirty-Ninth Report to the Legislature of Massachusetts Relating to the Registry and Return of Births, Marriages and Deaths in the Commonwealth, for the Year Ending Dec. 31, 1880; the Fifty-Ninth Report of Births, Marriages and Deaths in Massachusetts, for the Year 1900, and the Annual Report on the Vital Statistics of Massachusetts for the Year Ending Dec. 31, 1930.

3. The group of chronic diseases includes the cardiovascular-renal diseases, cancer, diabetes and respiratory tuberculosis; the selected acute diseases include the diarrheal diseases: diarrhea, dysentery, enteritis, cholera and cholera infantum; the communicable diseases of childhood: measles, scarlet fever, whooping cough, diphtheria and croup; and the following respiratory diseases: influenza, bronchitis and pneumonia.

4. The change in the age distribution of the population of Massachusetts which has taken place during this period is indicated by the following figures, taken from the census of Massachusetts, 1880, compiled by authority of the legislature from the Returns of the Tenth Census of the United States, Boston, 1883; Fifteenth Census of the United States, 1930, Washington, D. C., Government Printing Office, 1933, Vol. 2:

Age	Percentage of Total Population 1880	1930
45 years and over.....	21.6	26.6
65 years and over.....	5.4	6.5

7. A preliminary report on the hospital survey has been published. Mountain, I. W.: Business Census of Hospitals, Hospital 10: 19-21 (Nov.) 1936.

8. The surveyed cities are located in nineteen states, in three of which the survey has been extended also to twenty-three rural counties.

From the Office of Statistical Investigations of the United States Public Health Service. Published by permission of the Surgeon General.

1. The project is being executed with the aid of grants from the Works Progress Administration, under the general direction of the senior author. The scope of the survey has been described in detail in the Annual Report of the Surgeon General of the United States Public Health Service for 1936. Dr. Selwyn D. Collins, director of the Office of Statistical Investigations, and Rollo H. Britten, senior statistician of the United States Public Health Service, and Clark Tibbitts, field director of the survey, gave their advice and assistance.

of the problem of chronic disease in old age will indicate the extent of the burden which the costs of medical care impose on the needy aged. The study of disabling illness among persons of the working ages will throw light on chronic disability as a factor in unemployment and the state of dependency which is the frequent outcome of incapacitating illness in the wage-earner. While significant observations on the problem of chronic illness in the general population must await the study of more extensive records, it seems of interest at this time to present the preliminary results of the survey in a northern industrial city as an indication of the broad lines along which further analysis will proceed.

THE CHARACTERISTICS OF THE SURVEYED COMMUNITY

The city selected for preliminary study is a stable, industrial community in the North having a population of some 150,000 persons in the census of 1930. Approximately one ninth of the population,⁹ including some 18,000 persons in 5,118 families, was canvassed by the house-to-house method, 98 per cent of the schedules being returned during the period November 1935 through February 1936. The sample was obtained by an arbitrary division of the census enumeration districts into units having an average population of 750, every ninth unit being completely canvassed. Social and economic data and records of illness and medical services for a twelve months' period were obtained by the enumerator from a responsible informant for each member of the family.

The surveyed group resembles the city as a whole in color and nativity, being predominantly a white population with persons of native birth forming 74 per cent of the total. The proportion of children in the sample was somewhat lower, and the proportion of old persons higher, than obtained in the city as a whole in the census of 1930. The birth rate of the surveyed population was of approximately the same order as that for the entire city in 1935; the death rate was lower than the city rate, a low death rate being frequently observed in the experience of sickness surveys.

TABLE 1.—Chronic Disease and Major Orthopedic Impairments (Sole, Primary or Contributory Diagnosis)

Type of Case	Cases per 1,000 Persons
Total, disabling and nondisabling.....	279
Status on the day of the canvass:	
Disabling	23
Nondisabling	256
Status in the survey year:	
Disabling for a minimum of 7 consecutive days.....	49
Disabling for less than 7 consecutive days, or nondisabling	230

The predominating occupational group comprises skilled and semiskilled workers. On the day of the canvass, 71 per cent of the family heads were employed and 14 per cent were unemployed or receiving work relief. Nine per cent of the unemployed heads reported that they were unemployed because of disability. During the survey year, 15 per cent of all surveyed families had been on relief. A total of 45 per cent of the families reported an annual income of \$1,000 or less, and only 5 per cent had an annual income in excess of \$3,000.

THE LEADING CAUSES OF CHRONIC DISABILITY

The average prevalence of chronic disease and gross impairments in the surveyed community may be broadly

indicated by the fact that 22 per cent of the surveyed population, or approximately one in every five persons canvassed, was reported to have a chronic disease, a permanent orthopedic impairment or a serious defect of vision or of hearing, the symptoms of which had been recognized for at least three months. The chronic diseases and impairments enumerated represented both

Chart 2.—Incidence of disabling illness by cause. Illnesses disabling for seven consecutive days or longer in the survey year, including deaths, classified in broad groups as acute (symptoms of less than three months' duration) and chronic (symptoms of three months' duration or longer) by cause—sole, primary or contributory diagnosis. Orthopedic cases are exclusive of impairments of fingers and toes.

disabling and nondisabling chronic pathologic conditions known to the informant,¹⁰ the impairments including serious defects of vision and of hearing and lost or permanently impaired members or parts of the body. Approximately 4 per cent of the surveyed population had been disabled for one week or longer, and 1 per cent had been disabled continuously throughout the year as a result of chronic disease or permanent impairments due to disease or injury.¹¹

The prevalence of chronic disease increases with age, reaching a maximum among persons aged 65 and over. A chronic disease or gross impairment was reported for 58 per cent of all persons aged 65 and over, and 13 per cent of persons in this age group had been disabled by chronic disease for one week or longer in the survey year. The proportion of chronic invalids was likewise higher among the aged; 5 per cent of all persons aged 65 and over, or 9 per cent of all persons of these ages having a chronic disease, had been disabled continuously for at least twelve months. The proportion of chronic

10. In each case of illness for which permission was obtained for medical follow-up, the medical attendant was queried for confirmation of the diagnosis reported by the informant as the cause of illness. In this preliminary study the informant's diagnosis has been accepted, since returns of the medical reports were incomplete during the period of preparation. A hand tabulation of a random sample including 1,270 medical reports received from 140 physicians in five of the surveyed cities indicates confirmation of the informant's diagnosis in 86 per cent of the cases. In an illness due to multiple causes, the informant's designation of the diagnosis which was the most important cause of disability was taken as the primary cause of illness.

11. The distribution of persons disabled for more than twelve months, by the duration of disability from the month of onset to the month in which the canvass was made, is given below; twenty persons confined in institutions are included:

Duration of Disability	Number	Per Cent
1 year, less than 2.....	35	21.9
2 years, less than 3.....	22	13.8
3 years, less than 4.....	17	10.6
4 years, less than 5.....	15	9.4
5 years, less than 10.....	45	28.1
10 years or longer.....	26	16.2

9. A preliminary announcement of the survey contained a reproduction of the survey schedule and the original list of cities to be canvassed. The New Health Survey, J. A. M. A. 105:1127 (Oct. 5) 1935.

invalidity among the aged was of approximately the same order in the Massachusetts chronic disease survey,¹² 8.1 per cent of all sick persons aged 70 and over being completely disabled at the time of the 1930 survey, the corresponding figure for 1931 being 7.4 per cent.¹³

A more exact measure of the prevalence of chronic disease is derived from the records of the total cases enumerated in which count is made of the diagnosis of

each disease present in an individual suffering from several chronic diseases of simultaneous or successive development. The total case rate for all sole, primary or contributory diagnoses¹⁴ of chronic disease or major orthopedic impairments prevalent on the day of the canvass was 279 per thousand persons; the prevalence rates for cases classified by disability status on the day of the canvass and in the survey year are given in table 1.

As a contribution to the practical program of chronic disease control it is essential that we attempt to define the specific chronic diseases which in the experience of the surveyed community appear to demand special consideration. In establishing the relative importance of the chronic diseases, two bases of comparison are available: the first, frequency of occurrence; the second, severity in terms of the resultant disability. Our major interest obviously centers in the chronic diseases that cause the largest amount of disability. We may, however, consider the most frequently reported diseases first, subsequently evaluating them in terms of severity.

Rheumatism, chronic diseases of the respiratory and digestive systems, the cardiovascular-renal diseases and minor circulatory diseases¹⁵ account for approximately three fourths of all cases of chronic disease observed in the surveyed population.¹⁶ The high relative fre-

quency of these diseases is shown in chart 1. Among the most frequently reported diseases, the rates for non-disabling cases and cases disabled for less than seven consecutive days, shown in the cross-hatched portion of the bars, greatly exceed those for disabling¹⁷ cases, indicating that a large volume of chronic disease prevalent in the population is of a low order of severity. However, the relation between the disabling and the total case rate varies widely among the chronic diseases studied. Thus, the nervous diseases show a disabling case rate which is 62 per cent of the total case rate, while the disabling case rate for rheumatism is only 9 per cent of the total case rate.

The order of importance of the chronic diseases as causes of disabling illness is more clearly apparent from a consideration of the lower section in chart 2. A new alinement of the chronic diseases results from the exclusion of nondisabling cases. Rheumatism, which was observed to be the most frequently reported chronic disease, is outranked in frequency by diseases of the heart and arteries and the nervous and digestive diseases, when the causes of chronic disabling illness only are considered.

On the other hand, cancer,¹⁸ diabetes and tuberculosis, which our mortality experience indicates are important causes of death, were relatively infrequent in the surveyed population; both the total and the disabling case rates due to these causes are seen to be relatively low. The magnitude of the disabling case rate is thus an insufficient measure of the relative severity of the chronic diseases. Additional criteria are available in the total days of disability resulting from chronic illness during a year, and in the annual bed days, which may be distributed by specific cause of illness; a further evaluation of severity may be made by relating the annual volume of disability for a specific chronic disease

Chart 3.—Prevalence of gross impairments. Sole, primary or contributory diagnosis.

to the number of disabling cases of the given diagnosis, resulting in an annual average of days of disability per case. These figures for the survey experience are shown in table 2. While cancer, diabetes and tuberculosis contributed relatively little to the annual volume of chronic disability, owing to their low incidence, the average annual amount of disability per case for each of these

12. Bigelow, G. H., and Lombard, H. L.: *Cancer and Other Chronic Diseases in Massachusetts*, Boston and New York, Houghton, Mifflin Company, 1933.

13. The combined surveys of 1929-1931 in Massachusetts indicated that 29 per cent of persons aged 40 and over were sick with chronic disease. In the present survey, gross impairments as well as chronic diseases were recorded, resulting in a higher crude prevalence rate; thus, 42 per cent of persons aged 45 and over were reported to have a chronic disease or gross impairment.

14. The diagnosis of the sole chronic disease or major orthopedic impairment present is included, as is the diagnosis for each chronic disease or major orthopedic impairment present in an individual having more than one disease or impairment. In the latter case one diagnosis is designated as primary, the remaining diagnoses as contributory.

15. Hemorrhoids, varicose veins and other diseases of the lymphatic and circulatory systems (exclusive of diseases of the heart and coronary arteries, and arteriosclerosis) are included in this group.

16. In the classification of illness by cause, based in general on the International List of Causes of Death, 1929 revision, certain major departures were made as follows: cerebral hemorrhage and its subtiles are included with diseases of the heart and arteries; neuralgia and neuritis, lumbago and related conditions are included with rheumatism; the diseases of the veins and lymphatic system and other diseases of the circulatory system are grouped under the minor circulatory diseases. See also footnote 22.

17. In the subsequent discussion, the use of the term disabling is restricted to cases disabled for a minimum of seven consecutive days in the survey year; in this category are included all confinement, hospital and fatal cases without reference to the duration of disability. "Disabling" is used in the sense of inability to work or pursue usual activities.

18. The total disabling illness rate for cancer, including additional cases with symptoms of less than three months' duration, was 1.3 per thousand persons.

diseases was relatively high. On this basis, cancer, diabetes and tuberculosis rank in importance with the cardiovascular-renal group, nervous diseases, chronic digestive diseases, rheumatism and orthopedic cases and accidents as important causes of chronic disability. These causes considered as a group accounted for 73 per cent of the annual days of disability due to chronic illness and 81 per cent of the annual bed days. A comparison of the annual average days of disability per case for the various chronic diseases indicates that, in this experience, tuberculosis, the nervous diseases and the group including orthopedic cases and accidents show the highest severity, measured by this criterion. It is of interest that these diseases comprise the group for which some measure of public supervision exists in most communities, indicating that their importance as causes of severe disability is generally recognized. The severity of the nervous diseases is of special interest in relation to their etiology, in which syphilis is an important factor.¹⁹

Chart 4.—Percentage distribution of orthopedic defects according to major causes. Automobile and street accidents include also other public accidents.

A Broad Classification of Acute and Chronic Disease.—The distinction between acute and chronic disease is not susceptible of exact definition, but for statistical purposes an approximate classification is often desirable. In general, illness due to typically acute diseases is characterized by the sudden onset and early resolution of pathologic symptoms, while the disease processes resulting in chronic disease develop slowly, and may be arrested, but do not disappear. A broad separation of acute and chronic diseases may thus be made with reference to the duration of the disease symptoms, permitting a comparison of the characteristics of acute and chronic illness when insufficient data prevent the study of specific causes. The effectiveness with which a classification of illness on this basis segregates the important acute and chronic diseases is shown in chart 2. The designation of diseases with symptoms of three months' duration or longer as a predominantly chronic group appears to be justifiable, since the majority of the observed cases of such diseases as rheumatism, the cardiovascular-renal diseases, asthma, tuberculosis, cancer and diabetes fall within this class.²⁰ Cases of these

chronic diseases presenting symptoms of short duration, representing a recent onset of the disease process, show relatively low rates compared with those for cases of long duration. On the other hand, the most frequently reported diseases and conditions with symptoms of short duration are of a typically acute nature and include principally the infectious diseases, colds, acute bronchitis, tonsillitis and pneumonia (predominating in the respiratory group), conditions associated with the puerperal state, and accidents. These diseases comprise the group reported as the leading causes of illness in earlier sickness surveys;²¹ segregated from the chronic conditions by the short duration of their disease symptoms, they now appear as the leading causes of acute illness.²²

THE PREVALENCE OF GROSS IMPAIRMENTS

Orthopedic conditions and current accidents have been shown to be a major cause of chronic disability in the surveyed population, ranking in importance with the cardiovascular-renal and nervous diseases. Thus from the broad standpoint, accident prevention and the adequate control of diseases resulting in physical handicaps hold great possibilities for the reduction of chronic disability.

In the present survey an attempt was made to obtain complete records of serious defects of vision and hearing and permanent impairments of the skeleton and neuromuscular system, including lost and impaired members or parts of the body, the latter being considered for convenience in the group of orthopedic conditions. Both disabling and nondisabling permanent impairments incurred during the survey year and in prior years were enumerated. The results of this census are thus of special interest, since they represent the total permanent effect of disease and injury over the entire lifetime of the surveyed population. They are unique also in that they relate to the total population, the usual census of crippling conditions being restricted to those prevalent among children.

Orthopedic cases involving major and minor impairments were reported by the surveyed group more frequently than serious defects of either vision or hearing, the total case rate for orthopedic conditions being 25 per thousand persons, compared with a rate of 17 for defects of hearing, and 8 for defects of vision. The relative frequency of the specific impairments observed is shown graphically in chart 3. Major orthopedic conditions, involving impairment or loss of the organs of locomotion, hands, arms and trunk, show a total case rate of 15 per thousand persons. The degree of functional maladjustment resulting from these conditions is indicated by the disabling case rate, 3 per thousand persons, which represents 20 per cent of the total rate.

21. Sydenstricker, Edgar: A Study of Illness in a General Population Group: Hagerstown Morbidity Studies No. 1. The Method of Study and General Results, Pub. Health Rep. 41:2069-2088 (Sept. 24) 1926. Collins, S. D.: Causes of Illness in 9,000 Families, Based on Nationwide Periodic Canvasses, 1928-1931, *ibid.* 48:283-308 (March 24) 1933.

22. The effective use of the duration of the disease symptoms in separating acute from chronic diseases is apparent in the case of disease groups predominantly acute, such as the infectious diseases, or chronic, such as the diseases of the heart and arteries. The result of this classification is somewhat obscured when less homogeneous groups, such as the respiratory and digestive diseases, are employed. Examination of the specific diseases in these diagnosis groups indicates that the segregation of acute from chronic conditions on the basis of duration of symptoms is equally effective. Among the "long duration" digestive diseases, ulcer of the stomach and chronic conditions of the gallbladder predominate; "short duration" digestive diseases include a majority of typically acute conditions—appendicitis, acute stomach disorders, and diarrheal diseases. The "long duration" respiratory diseases include sinus infection and a variety of chronic conditions of the respiratory tract, "short duration" respiratory diseases including principally colds, acute bronchitis, tonsillitis and pneumonia. In both groups a small number of chronic diseases of recent onset is included among the "short duration" cases.

19. Satisfactory reporting of syphilis is not obtained by the method of the house-to-house canvass. In the present survey, only one case of syphilis was reported, although supplementary data, made available by Dr. Joseph W. Mountin from the study of health facilities being conducted under his direction, indicate that approximately 100 persons in the survey area received treatment for syphilis in the local health department clinic.

20. In the census of chronically ill persons under the care of medical and social agencies in New York City, 95 per cent of the group reported a duration of disease symptoms of three months or longer. See Jarrett, Mary C.: Chronic Illness in New York City, vol. 1: The Problems of Chronic Illness, appendix IV, table 5, New York, Columbia University Press, 1933.

Furthermore it has been shown that the volume of chronic disability resulting from these disabling cases is high.

The relative importance of accidents and certain specific diseases as causes of impairments is shown in chart 4. In the surveyed population of all ages, accidents, considered as a group, were of relatively greater frequency as a cause of impairments than any specific disease. When impairments were classified by cause in broad age groups it was found that certain specific

among school children, young adults, persons of middle age and the aged? To what extent does the problem vary according to dependency status and income? What is the importance of chronic illness in relation to unemployment?

Age and Sex Incidence.—When all chronic disabling illnesses are classified by age, one finds that 10 per cent of all cases occur among children under 15, 7 per cent among young persons between the ages of 15 and 25 years, and 83 per cent among adults. Distribution of

diseases, such as poliomyelitis and congenital causes, ranked in importance with accidents as causes of impairments among young persons under 25 years of age. This will be shown in the subsequent discussion of the variation in prevalence of gross impairments with age. The data indicate that the campaign for the reduction of accidents, the early registration and adequate treatment of congenital defects and the supervision of cases of poliomyelitis constitute an important part of a community plan for the control of chronic disease.

THE GROUPS CHIEFLY AFFECTED BY CHRONIC DISEASE

The formulation of a program for the control of chronic disease must be based on knowledge of the groups of the population chiefly affected by chronic illness. What is the comparative severity of the problem

the cases occurring among adults by broad age periods shows that 33 per cent of these cases occur among young adults (from 25 to 44 years); 37 per cent among persons of middle age (from 45 to 64 years), and 30 per cent among persons aged 65 and older. Thus, while the number of cases occurring among young persons is by no means negligible, the cases are largely concentrated among adults, falling in approximately the same proportion among young adults and persons in middle and old age.

Old age, however, is the period of maximum incidence of chronic illness, since the number of the population exposed declines progressively from childhood to old age. The curves of acute and chronic disabling illness by age and sex are shown in chart 5; the annual disabling illness rates are presented in table 3. The

characteristics of the age curve of chronic disabling illness differ essentially from those of the curve of acute illness, which shows a maximum incidence in youth. In general, the incidence of chronic disabling illness in this series is higher among females than among males.²³ A similar excess²⁴ in the prevalence of chronic disease among females was observed in the Massachusetts survey.¹²

Chart 5.—Age and sex incidence of disabling illness classified in broad groups as acute and chronic—all causes, sole or primary diagnosis only.

Variation in Annual Duration of Disability with Age.—In connection with the variation of chronic illness with age the question arises, To what extent are the most frequent illnesses also the most severe illnesses in terms of annual days of disability. The data presented graphically in chart 6 (table 4) show the effect of distributing the annual days of disability at a given age, first among the total population exposed, including both sick and well persons, and secondly among illnesses in the corresponding age group. Distributed over the entire surveyed population, both sick and well, the average annual amount of disability due to chronic illness is about six days per person compared with three days per person for acute illness.²⁵ An even greater contrast is presented on the basis of sick persons only, the average disabling duration of the chronic case being nearly five months compared with three weeks for the average acute case.

The relation between volume of disability and the total population exposed at a given age closely parallels the variation in age incidence. Persons aged 65 years and over were disabled by chronic illness, on the average, for twenty-seven days during the year, compared with nine days for persons of middle age (from 45 to 64 years), and five days for young adults (from 25 to 44 years). Among the aged, the volume of disability due to patients disabled continuously for twelve months accounts for 65 per cent of the total annual days of disability due to chronic causes. The elimination of these cases of chronic invalidity among persons aged 65 years

and over reduces the average annual days of disability for this age group to nine days per person.

When the average chronic case is considered, the annual days of disability vary from a minimum of slightly over three months per case among children under 15 to a maximum of approximately six months per case for persons aged 65 years and over, with an average of approximately five months per case for persons of all ages. However, the variation in the annual days of disability of the chronic case with age is greatly reduced if cases disabled for twelve months are excluded. The average annual amount of disability per case among persons aged 65 years and over is reduced to slightly over three months by the elimination of cases of chronic invalidity, compared with an average of approximately two and one-half months per case for persons under 15 years of age. The frequency of cases of chronic invalidity among the aged results from the high incidence of the more severely disabling chronic diseases in this age period, a fact which will be brought out in the subsequent consideration of the variation in types of chronic disease with age.

Chronic Disabling Illness Classified by Cause and Age.—Are the specific chronic diseases equally important at all ages, increasing from youth to old age merely in frequency and severity, or do the chronic diseases characteristic of old age differ in type from those predominating in youth or middle age? A consideration of the distribution of chronic disabling cases by cause and age, shown in chart 7, indicates the major importance among the aged of the so-called degenerative diseases, including the cardiovascular-renal group, cancer and diabetes. This group occurs with less frequency in middle age, the proportion for persons aged from 45 to 64 years being 29 per cent, compared with 48 per cent for persons aged 65 years and over. It is notable, however, that 17 per cent of the disabling cases of degenerative disease fall in the young adult period, confirming the indication of mortality rates that the degenerative processes associated with advancing age do not constitute the sole etiologic basis of these diseases. The prevention of the cardiovascular-renal diseases through the control of such diseases as acute rheumatic fever, syphilis, the communicable diseases of childhood

Chart 6.—Incidence and severity of disabling illness classified in broad groups as acute and chronic according to age—all causes, sole or primary diagnosis only. Severity expressed as annual days of disability per person and per case of specified type.

23. It is of interest, to note that the peak in the curve of acute illness among females of the young adult ages, due to the disability associated with childbirth, does not appear in the curve of chronic illness, indicating the effective separation of acute and chronic conditions by classification of illness according to duration of disease symptoms.

24. The sex differential may be explained in part by the greater completeness of illness records for women resulting from the fact that the majority of the informants were women. Thus, Brundage's study of the sickness experience of members of sick benefit associations in which the requirements for eligibility for sick benefits were the same for the two sexes does not show a consistent excess in the female rate for the specific chronic diseases studied. The female rate exceeded the male rate for diseases of the nervous system and cancer, but an excess occurred among males for rheumatism and allied conditions. The rates for the cardiovascular-renal diseases were approximately the same for the two sexes. (Brundage, D. K.: *Sickness Among Industrial Employees: A Summary of the Morbidity Experience from 1920 to 1927*, Pub. Health Rep. #4: 387-403 [Feb. 22] 1929.)

25. The figures are based on the annual days of disability resulting from illnesses disabling for a minimum of seven consecutive days. In the survey of the Committee on the Costs of Medical Care,¹⁴ illnesses of this category accounted for approximately 90 per cent of the total annual days of disability.

and typhoid holds much promise as a method of reducing chronic illness due to this important disease group. Disabling conditions included among orthopedic cases and accidents show the highest proportion of cases among persons of middle age. Nervous and respiratory diseases, on the other hand, show a concentration of cases in the young adult period, with a relatively high proportion of cases under the age of 25 years.

Age Prevalence of Major Orthopedic Impairments.—The proportion of persons having permanent impair-

ments increases with age, since the impairments enumerated are cumulative, representing the effect of disease and injuries incurred in prior years in addition to impairments of current origin. The proportion of persons with major orthopedic impairments is shown in table 5 for certain age groups; the figures are based on both disabling and nondisabling defects.

When major orthopedic impairments were classified by cause for certain broad age groups, it was found that accidents predominated as a cause of impairment among adults, while certain specific diseases, such as poliomyelitis and congenital conditions ranked in importance with accidents as causes of orthopedic defects among young persons. The figures are shown in table 6. Among persons aged 25 years and over the case rate for major orthopedic impairments due to accidents was approximately six times as large as the rate for young persons under the age of 25, while the case rate for major orthopedic impairments due to poliomyelitis was approximately of the same magnitude for young persons and adults. Major impairments of a congenital nature likewise showed no appreciable difference in the case rates for young persons and adults. On the other hand, one of every four impairments of young persons under the age of 25 years was due to poliomyelitis, compared with a ratio of one in ten for adults, while accidents caused approximately one in every five impairments among young persons and one in every two recorded for adults.

Economic Status.—The evidence at hand indicates that the frequency and severity of illness is greater among the poor than among those in the high income groups. Thus, special analysis of the records of the Committee on the Costs of Medical Care showed an inverse relation between income class and annual per capita days of disability.²⁶ In the Massachusetts surveys of 1930 and 1931,¹² the prevalence of chronic disease among persons over 40 years of age showed a consistent increase with decreasing economic status.

While a complete analysis of the relation between social and economic factors and chronic illness must await more extended study of the survey records for additional cities, the experience of the present community is of some interest. The figures shown in table 7 indicate a higher incidence of disabling illness and a larger average amount of disability in the relief groups than in the nonrelief groups, the excess being more marked in the case of chronic than of acute illness. A similar concentration of persons with chronic disabilities in the relief population has been observed in a survey of Dayton, Ohio.²⁷

The disabling illness rates classified by relief status and income for a group of the more seriously disabling chronic diseases are shown in table 8.

The figures indicate that the higher average annual days of disability due to chronic illness observed in the relief population results from the excess in the incidence of the more serious chronic diseases in this low income group.

Chronic Disability as a Factor in Unemployment.—The part played by incapacitating illness and injury of the wage-earner in the creation of family dependency is suggested by a comparison of the incidence of chronic illness among unemployed and employed persons. The figures shown in table 9 indicate a marked excess in the incidence of chronic disabling illness among the unemployed in all income groups;²⁸ on the other hand, there is no difference of statistical significance between

hospital facilities, the scope and interpretation of local and state welfare and public health laws and the average income of the population. In the following summary, certain facts relating to the nature and extent of facilities for care of the sick in the surveyed community are presented as a basis for the interpretation of the subsequent discussion:

Physicians²⁹ in the county in which the surveyed community is located showed approximately the same ratio to the population as that obtaining for the country as a whole in 1935.³⁰

General and special hospital facilities²⁹ in the county were definitely higher than the average for the country as a whole in 1935.³¹

Tuberculosis and mental hospital facilities²⁹ in the state were somewhat above the average for the country as a whole in 1935;³¹ however, the beds available per capita for both types of case were approximately 20 per cent lower than the number recommended in a recently proposed standard of adequate care of the tuberculous and the mentally diseased.³² A total of 96 per cent of the beds for mental cases and 81 per cent of the beds for the tuberculous in all institutions in the state were

government owned. Hospitalization of the tuberculous is a function of the health department and is available without the restriction of indigency.

Clinic service for the tuberculous and the venereally diseased is provided by local governmental agencies; a mental hygiene clinic is conducted by a local hospital with the aid of state-subsidized personnel. Patients are admitted to these clinics without restriction as to economic status. An emergency medical and surgical clinic operated by the County Relief Commission provides medical care for the relief population and the medically indigent; 79 per cent of all clinic visits made by residents of the surveyed city and county in 1935 were made to this clinic.³³ An outpatient service for indigent orthopedic cases is conducted by a local hospital with partial reimbursement for service from state and federal funds, the latter made available by the Social Security Act.³³

The survey data do not permit satisfactory comparison of the volume of medical services received by low income groups with that received by groups in which the amount of medical service purchased is not restricted by economic factors, since the size of the sample of persons in the higher income classes is relatively small.

The experience of the surveyed community is obviously an isolated one, applicable only to areas of similar economic level, with health facilities of comparable adequacy. In spite of their limitations the results are of interest as an indication of certain broad problems involved in community care of the chronic sick.

Medical and Nursing Care for Acute and Chronic Illness.—In the surveyed population, care was given by a physician in 79 per cent of all disabling illnesses, both acute and chronic, and hospitalization in 18 per cent during the year preceding the date of the survey. A special analysis of data relating to illnesses disabling for a minimum of six days recorded in the survey of the Committee on the Costs of Medical Care³⁴ indicates that in 86 per cent of these illnesses the care of a physician was given and in 20 per cent hospitalization

§ Data not available.

private bedside nursing care was also found to assume a relatively unimportant rôle in the care of the chronic sick.³⁵

The burden of chronic disease in lost time and cost of medical and nursing care may be inferred from the comparison of services for acute and chronic illnesses presented in table 11 and shown graphically in chart 8. While only approximately one fourth of the disabling cases and somewhat over one third of the hospitalized cases were chronic illnesses, these cases accounted for over two thirds of the total days of disability experienced by the surveyed population and four fifths of the total days of hospitalization. Expressed in terms of annual hospital days per case, in the average acute case only nine days of hospital care was given during the year, compared with sixty-three days in the average chronic case exclusive of old cases hospitalized throughout the entire twelve months period. A similar disparity exists between the proportion of acute and chronic illnesses among physicians' and private nurses' patients and the relative volume of physicians' calls and bedside nursing days given in acute and chronic illness. Only 25 per cent of the illnesses attended by private or clinic physicians were chronic, but 51 per cent of the physicians' annual services were received by the chronic sick. Chronic cases represented only 35 per cent of all illnesses in which private bedside nursing care was given but absorbed 71 per cent of the annual bedside nursing days. In the case of visiting nurse care, however, patients with acute illnesses predominated among those attended and also received the major volume of annual services.

A comparison of the proportion of medical services received by patients with the various chronic diseases, shown in table 12, indicates that the supply of medical care is adjusted to the severity of the case. A total of 71 per cent of all physicians' calls in chronic cases were received by patients with the major chronic diseases—

the cardiovascular-renal group, cancer, diabetes, tuberculosis, the nervous and digestive diseases, rheumatism and the group including orthopedic cases and accidents. A notable difference is observed in the type of chronic case predominating among hospitalized cases. Orthopedic cases and accidents, cases of nervous disease and tuberculosis account for 74 per cent of the total hospital days in all chronic cases, indicating the recognized importance of institutional care in cases of this type, and the relatively extensive hospital facilities available to residents of the surveyed community.

While the small number of chronic cases in which nursing care was given in the surveyed community limits the extent of the analysis of data on nursing care, certain important facts may be noted. During the survey year, a total of 2,533 days of bedside nursing care was given in forty-six chronic disabling illnesses, representing an average of fifty-five bedside nursing days per chronic case attended. Visiting nurses made 387 visits to forty-one chronic cases during the survey year, an average of approximately nine visits a case. Chronic cases of the degenerative and digestive diseases, nervous and orthopedic cases, and accidents absorbed approximately three fourths of the total annual bedside nursing days and one half of the total annual visits of visiting nurses which was given in all chronic disabling illnesses.

Variation in Medical Services with Relief Status and Income.—It has already been noted that medical care of the indigent in the surveyed community was provided by an organized clinic serving the relief population and the medically indigent. We therefore anticipate more adequate medical care among the poor in this emergency period than would prevail under the system of welfare administration operating in normal times. The figures in table 13 show the effect of the local system of medical relief; the average person on relief, including both sick

Chart 8.—Relative volume of medical and nursing services received for acute and chronic illness—percentage distribution of cases, days of disability and medical and nursing services classified by duration of symptoms.

and well, received more care for chronic illness from a private or clinic physician than the average person in the nonrelief population, with the exception of the highest income class. However, the relief population was found to receive less home care, the average number of home calls per person on relief being approximately one half the average for each person in the highest income class. When medical services for the various income classes are compared on the basis of the average chronic case attended, the relief population again shows a definitely lower average of care by a physician than the group with an income in excess of \$2,000;

35. In 7 per cent of all illnesses recorded in the survey of the Committee on the Costs of Medical Care³⁴ the care of a private duty, practical or visiting nurse was given; the figure relates to all illnesses, both non-disabling and illnesses disabling for one day or longer. Data from this survey on nursing care for illnesses disabling for a minimum of six days have not been tabulated.

however, approximately the same amount of care by a physician was given in the average chronic case in the relief group as in the average case in the nonrelief "middle" income classes with incomes under \$2,000.

Persons in the low income groups received more hospital care for chronic illness than those in the upper income groups, measured both in terms of the average person exposed and the average patient hospitalized. The lower average of physicians' calls observed in the groups with incomes under \$2,000 is thus compensated for in part by the higher average of medical care received during hospitalization. The excess in the aver-

disease little organized supervision is given, with the exception of the local outpatient service available for the tuberculous, the syphilitic and the orthopedic and mental patients and the casual care provided for the relief population by the emergency relief clinic. Hospitalized chronic patients, with the exception of the tuberculous and the mentally diseased, are cared for in local general hospitals, since facilities in institutions specifically adapted to the requirements of the chronic sick are not available. There is no public agency responsible for the integration of services for the treatment of the chronic sick among the dependent groups of the popu-

age number of hospital days for the low income groups is greatly reduced by the exclusion of cases in institutions throughout the survey year. The liberal policy of the state in the care of the tuberculous and the high proportion of government-owned beds in hospitals for the tuberculous and the mentally diseased are reflected in the more favorable hospital experience of chronic cases in the low income groups.³⁶

COMMUNITY ORGANIZATION FOR THE CONTROL OF CHRONIC DISEASE

The surveyed community has no coordinated plan for the care of the chronic sick. In early cases of chronic

lation. The large volume of hospital care absorbed by chronic cases, particularly among the low income groups, suggests the need for such centralized supervision, to the end that hospital care may be restricted to cases requiring institutionalization, while in other appropriate cases care in the home may achieve more effective results from the standpoint of treatment and its cost to the community.

SUMMARY

The United States Public Health Service has assembled reports of chronic disease and gross impairments in some 3,000,000 persons in ninety-two representative localities canvassed in 1935-1936, supplementing its observations on the prevalence and incidence of disabling illness with information on the present status of health department practice and the extent of local facilities for the care of the sick in the surveyed areas.

36. A high average amount of hospital care in the lowest income class has been previously observed. In the survey conducted by the Committee on the Costs of Medical Care,³¹ the lowest income class showed the highest average hospital days per person when the volume of hospital care in general and special hospitals was compared; exclusion of tuberculosis sanatoriums and mental hospitals resulted in a maximum for the class with an income over \$10,000, but the average hospital days per person for the lowest income class exceeded the figure for all other classes with incomes under \$10,000.

The results of the present preliminary report on a northern industrial city may be summarized as follows:

1. Approximately one in every five persons canvassed was reported to have a chronic disease, a serious defect of vision or hearing or a permanent physical impairment resulting from disease or injury.

TABLE 13.—*Medical Services for Chronic Disabling* Illness, Classified by Relief Status and Income (All Causes, Sole or Primary Diagnosis Only)†*

* Disabling for seven consecutive days or longer.

† The figures for illnesses, physicians' calls, hospital days and population on which this table is based, are presented in table 14.

‡ Includes cases and persons with income unknown.

§ Total physicians' calls include home, office or clinic services.

2. The problem of chronic disease reaches its greatest severity among the relief population and the aged. In the total population, one in every twenty-five persons had been disabled by chronic disease for one week or longer in the survey year; in marked contrast are the corresponding ratios of one in fourteen for the relief population, and one in eight for persons aged 65 years and over. Continuous disability for a period of twelve months or longer, due to a chronic disease or gross impairment, was reported by one in every 100 persons

were chronic, these cases accounted for over two thirds of the total annual days of disability recorded for the surveyed population and for four fifths of the annual hospital days. Chronic cases likewise absorbed one half of the annual services of physicians and almost three fourths of the annual bedside nursing days, although acute illnesses predominated among cases attended.

5. The types of chronic disease found to be most seriously disabling were the cardiovascular-renal group, cancer, diabetes, ulcer of the stomach and chronic diseases of the gallbladder, rheumatism, tuberculosis and the nervous diseases.

6. Permanent major orthopedic impairments, the result of both current and prior accident and disease, were reported by approximately one in 150 young persons under the age of 25 and by one in fifty adults aged 25 and over. One in every four major orthopedic impairments in young persons under the age of 25 was due to poliomyelitis, compared with a ratio of one in ten for adults; accidents caused one half of these impairments recorded for adults but only one in five impairments in young persons under the age of 25.

7. The favorable effect of the local system of emergency medical relief was apparent in the relatively large volume of physicians' services received by the average person in the relief population. However, the higher incidence of chronic illness in the relief group resulted in less care by a physician for the average chronic case than was given in the average case in the nonrelief population.

8. The surveyed city, in common with most American communities, has no coordinated plan for the control of chronic disease. The inertia of the community in the face of this major health problem results from lack of awareness of its magnitude, a situation arising in turn from the paucity of factual information concerning

TABLE 14.—*Annual Medical Services for Chronic* Disabling† Illness, Classified by Relief Status and Income (All Causes, Sole or Primary Diagnosis Only)*

† Disabling for seven consecutive days or longer in the survey year.

‡ Includes home, office or clinic services.

of all ages, while among the aged, one in every twenty persons had been a chronic invalid for at least twelve months.

3. The severity of chronic disability in the relief population reflects the inability of wage-earners in the low income groups to cope with the burden of unemployment due to incapacitating illness and injury. On the day of the canvass, approximately one in ten of the unemployed heads of families were unemployed because of disability. Approximately one in every ten unemployed males between the ages of 25 and 65 had been disabled by chronic disease for one week or longer in the survey year, while employed males of these ages were disabled in the ratio of one in fifty.

4. The burden of chronic disease in lost time and cost of medical and nursing care is indicated by the fact that while only one fourth of the disabling illnesses, and somewhat over one third of the hospitalized cases

the specific burden of chronic disease. By defining the problem in relation to the social and economic groups and the geographic areas in which it is most acute, the final analysis of the entire volume of data collected in the health survey should provide a basis for concerted community action in the control of chronic disease.

Delegated to Correlate the Teaching in Science.—We have gained much for science but have lost much for practice by the course we are following, and I look forward to a time when the pendulum will swing back, not to a day when the spirit of research will be any less active, but to a day when suitable representatives of the clinical departments will be delegated to correlate the teaching in the science courses so that their bearing on what is to come may be constantly kept in mind. A course in pure science unrelated to the patient belongs rather in the college than in the medical school.—Cushing, Harvey: *Consecratio Medici and Other Papers*, Boston, Little, Brown & Co., 1928.

Council on Pharmacy and Chemistry

ANNUAL MEETING OF THE COUNCIL ON PHARMACY AND CHEMISTRY

The Council on Pharmacy and Chemistry of the American Medical Association held its annual meeting at the Association headquarters, Friday and Saturday, March 12 and 13, 1937. Those present were:

Dr. David Barr	Dr. Paul Nicholas Leech
Dr. J. Howard Brown	Dr. G. W. McCoy
Dr. S. W. Clausen	Dr. E. M. Nelson
Dr. H. N. Cole	Dr. W. W. Palmer
Dr. C. W. Edmunds	Dr. William C. Rose
Dr. Morris Fishbein	

Dr. James S. McLester, member of the Council on Foods, and Dr. Olin West, General Manager, were also present.

Dr. Torald Sollmann was reelected chairman of the Council and Dr. W. W. Palmer was reelected vice chairman.

Among the many items discussed during the meeting, the following may be of interest both to physicians and to manufacturers:

A. M. A. Interns' Handbook.—The revision of "Hospital Practice for Interns" was discussed by the Council: details as to the general type of revisions to be made, format and other matters. The secretary of the Council on Medical Education and Hospitals reported that that council would be pleased to cooperate in the revision. The Council voted to change the name from "Hospital Practice for Interns" to "A. M. A. Interns' Handbook."

Brochures Issued by Pharmaceutical Houses.—There has recently been a tendency on the part of certain pharmaceutical firms to issue brochures advising the profession on the status of certain diseases and making recommendation for therapeutic treatment. In such brochures a certain drug is extolled, frequently to the exclusion of other therapeutic measures. The members of the Council felt that comprehensive reviews of medicine, surgery or the specialties are the function of duly qualified persons who undertake the task from altruistic motives rather than for the purpose of advocating the sale and use of particular commercial products. The members of the Council recognize the usefulness of educational brochures when prepared under proper auspices and with proper restrictions. The Council voted that the Committee on Rules and Procedure be instructed to bring before the Council a statement on this subject, with a view to including it in the explanatory notes of the rules of the Council.

Vitamins.—As announced previously, the Council on Pharmacy and Chemistry, in cooperation with the Council on Foods, has decided to sponsor a series of articles on vitamins. The Council voted that the proposed outline of the articles and the suggested authors be approved. It is anticipated that this series will be published in *THE JOURNAL* early in 1938.

Viosterol Preparations.—The Council's definition of Viosterol appears in the monograph under that heading in New and Nonofficial Remedies. The Council voted to amend this monograph, especially with reference to the definition, to read as follows:

"Investigations dealing with the chemistry and physiology of vitamin D led to the demonstration that ergosterol acquires antirachitic activity when subjected to ultraviolet irradiation. Ergosterol is a widely distributed plant sterol that was first isolated from ergot and the compound can readily be prepared from yeast. In 1929 the Council adopted the term 'Viosterol' to designate irradiated ergosterol. Since that time it has been demonstrated that other physicochemical processes may be used to change ergosterol to a product similar in physiologic, physical and chemical properties to irradiated ergosterol. Such forms of activated ergosterol, and irradiated ergosterol prepared by modifications of the original method, are designated as 'Viosterol' followed by a designation of the process used in their preparations. The term 'Viosterol in Oil' is used to designate viosterol dissolved in edible vegetable oil.

Therapeutically viosterol is a form of vitamin D and claims for this product are limited to the allowable claims for this vitamin given in the preceding general article, Vitamins and Vitamin Preparations for Prophylactic and Therapeutic Use.

It should be borne in mind that viosterol does not contain vitamin A and that harm from hypercalcemia may result from the use of excessive doses of the substance."

The Council believed this action necessary because activated ergosterol preparations made by processes other than ultraviolet irradiation (the Steenbock process) are being introduced. The Council voted however that, until such time as the products are proved to be chemically identical with that produced by ultraviolet irradiation or proved to be the isolated vitamin itself, a modifying phrase shall be included in the names, thus: "Viosterol (John Doe Process) in Oil."

Nomenclature for Vitamin B₁.—The Council considered the name "Thiamine Chloride," proposed by Dr. R. R. Williams, New York, as a designation for the crystals of vitamin B₁ hydrochloride. The Council tentatively approved the name but felt that Dr. B. C. P. Jansen of Utrecht, Netherlands, should be consulted before such a term is accepted. The Council wishes to accept a name satisfactory to Drs. Jansen and Williams which at the same time meets the objection of the Council to therapeutically suggestive names.

Cod Liver Oil in Malt Preparations.—The Council has ruled that if the vitamins are present in sufficient amounts to be therapeutically active, it is irrational to administer a preparation containing a combination of several vitamins, for instance, B and G with A and D. On the other hand, if the vitamins in the product are not present in therapeutically significant amounts, they should not be declared on the label in such a manner as to lead to the belief that they are therapeutically valuable. In accordance with this rule a concern was notified that it could not claim the presence of vitamins B and G in its cod liver oil and malt preparation since this preparation in question did not contain these vitamins in significant amounts. The firm, on the other hand, felt that since it had prepared its product with such care that it contained vitamins B and G it was entitled to mention them without claims for use in treatment. It was voted that cod liver oil and malt preparations be permitted to declare on the label that the product contains vitamins B and G but that it also be stated in connection with such declaration exactly what the vitamin B and G content is in terms of international units per gram, and that no other representations for vitamins B and G may be made.

Food and Drug Legislation.—The Council voted to reaffirm the statement published two years ago containing its platform on the revision of food and drug laws (*THE JOURNAL*, Jan. 12, 1935, p. 125).

Aminophylline.—The Council decided that after October 5 the therapeutic claims for all accepted products of aminophylline should be restricted to those recommending it for its diuretic effect and as a myocardial stimulant. The Council is of the opinion that there is no satisfactory evidence to show that aminophylline or other known theophylline preparation acts as a dilator of the coronary arteries or has an appreciable effect in reducing the pain of angina pectoris.

Insulin Preparations.—The Council discussed extensively the recent work on insulin compounds, in order to be in a position to pass on future developments. No action was taken.

Solution of Epinephrine 1:100.—The Council has been hesitant in accepting a solution of epinephrine 1:100 for fear that hazards might arise in the use of a preparation ten times as active as the usual solution of epinephrine 1:1,000. A number of questionnaires were sent out to consulting clinicians in reference to the problem. The Council voted that solution of epinephrine 1:100 be recognized for inclusion in New and Nonofficial Remedies, provided the advertising of firms submitting brands is conservative and contains warning statements.

Oral Vaccines.—The status of oral vaccines was reviewed by the Council. The Council was informed that a report on the literature had been prepared and was available. The Council asked that this report, augmented to include the most recent references, be presented for its consideration with view to sponsorship of a published statement.

Aminopyrine.—The Council is disturbed by the continued excessive claims for aminopyrine, particularly the recommendations for its use in dysmenorrhea, because of the danger of agranulocytosis arising from its use by some individuals. The Council voted to reaccept certain brands of aminopyrine with the understanding that all advertising shall include a suitable warning irrespective of where published and that the use of the drug in dysmenorrhea be not recognized as an acceptable recom-

mendation. The Council adopted the following statement to be included in N. N. R. 1938:

"Aminopyrine appears to produce serious and sometimes fatal granulocytopenia especially in susceptible individuals. The drug should therefore be withdrawn if a skin eruption, dizziness or chill occurs; it should not be administered in large doses or over a long period of time unless repeated leukocyte and differential counts are made at regular intervals. The drug should not be used in the treatment of dysmenorrhea."

Catgut Sutures.—The Council was notified that the Board of Trustees had provided an additional appropriation for the use of the Council in the investigation of catgut sutures. The Council authorized the Committee on Catgut Sutures to make a further report on the market supply of ligatures. The Council also recommended that the Board of Trustees urge the passing of suitable legislation placing the responsibility of control of catgut sutures under an appropriate government agency.

Therapeutic Research.—The report of the Council on Therapeutic Research (*THE JOURNAL*, May 1, 1937, p. 1535) was received and expression of appreciation conveyed to the members of the Committee for the work done.

Control and Administration of Patents.—The Council discussed extensively the patent situation in the United States and particularly certain cases in which patents are held by organizations for purposes of licensing. The Council voted that a report be formulated for consideration with view to publication.

Reports of Committees on Publications of the Council on Pharmacy and Chemistry.—The Council considered the reports in reference to the *Epitome of the Pharmacopeia* and *National Formulary*, *Useful Drugs*, and *Glandular Therapy*. It was gratifying to note the unprecedented response on the part of the profession and students to the issuing of these books, as well as to *New and Nonofficial Remedies*.

REPORT OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT.
PAUL NICHOLAS LEECH, Secretary.

SULFANILAMIDE AND RELATED COMPOUNDS

The Council on Pharmacy and Chemistry, noting the variety of proprietary names for para-amino-benzene-sulfonamide, adopted the term "Sulfanilamide" as a nonproprietary name for this chemical (*THE JOURNAL*, April 17, p. 1340). The Council decided that it was advisable to issue a report on the present status of this substance and the related compounds which are used for similar purposes. Subsequently, several brands of the chemical were submitted to the Council under the name Sulfanilamide, and Winthrop Chemical Company submitted its brand under the name Prontylin. These brands will be the subject of reports to be issued later.

The following firms have submitted Sulfanilamide: Calco Chemical Co., Inc., Lederle Laboratories, Inc., Eli Lilly and Company, Inc., Merck & Co., Inc., Parke, Davis & Company and E. R. Squibb & Sons.

For the purpose of discussion and because of the confusing terminology for the related compounds, the following terms are defined:

Sulfanilamide: The nonproprietary name adopted by the Council for para-amino-benzene-sulfonamide, also known as para-amino-phenyl-sulfonamide, Prontylin (Winthrop) and Prontosil Album (Bayer). It is also marketed under the following names: Stramid (Alba Chemical Company), Streptocide (Evans Sons Lescher & Webb, Ltd., London), Colsulanyde (Crookes Laboratories, London), Sulfamidyl (Abbott Laboratories) and Sulphonamid P (Burroughs, Wellcome & Co.). It is regretted that certain firms in America are using proprietary names.

Prontylin: Sulfanilamide. The proprietary name of Winthrop Chemical Company, Inc., for its brand of Sulfanilamide.

The original Prontosil:¹ This chemical is the hydrochloride of 4-sulfamido-2':4'-diaminoazobenzene. It has a solubility in water of 0.25 per cent and was marketed in the form of red tablets.

Prontosil: A name applied in this country by the Winthrop Chemical Company to the red dye, the disodium salt of 4-sulfamido-phenyl-2'-azo-7'-acetyl-amino-1'-hydroxynaphthalene-3':6'-disulfonic acid, which is referred to in European literature as Prontosil Soluble (Prontosil S.) and Streptozon S. The Winthrop Chemical Company, Inc., does not market its Prontosil in powdered form but does market Prontosil solution containing 2.5 per cent of the red dye.

Rubiazol: A compound used by the French workers, which is stated by the Winthrop Chemical Company to have been a French duplicate of the original Prontosil.

Experimental work on the therapeutic use of these compounds started with the work of Domagk,² who studied the effect of the original Prontosil on mice infected with hemolytic streptococci of human origin. A general review of subsequent studies on related compounds administered to mice as well as to human beings has been the subject of two editorials in *THE JOURNAL*.³ Because of their greater solubility, convenience of administration, lesser toxicity and the more favorable results obtained, Prontosil Soluble and Sulfanilamide rather than the original Prontosil have been used in most of the recent experiments. In fact, it has been suggested that the anti-streptococcal activity of the azo compounds, Prontosil and Prontosil Soluble, is a result of their being reduced in vivo or in vitro into Sulfanilamide, which seems to be the active compound,⁴ although Gley and Girard find the activity of one azo derivative inexplicable by the hypothesis that para-amino-benzene-sulfonamide is the only active derivative. (*Presse méd.* 44:1775 [Nov. 11] 1936.) It so happens that Sulfanilamide is suitable for administration to human beings either parenterally or orally. When administered subcutaneously or orally it appears as such in the blood stream within a few hours, and at a somewhat lower concentration in the cerebrospinal fluid. There is evidence which indicates that in man it is excreted in the urine, partly as Sulfanilamide and partly in a conjugated form, probably para-acetylaminobenzene-sulfonamide.⁵

The nature of the antibacterial action of Sulfanilamide is not yet completely understood. Long and Bliss⁶ report that Sulfanilamide in dilutions of 1:10,000 or more is bacteriostatic in vitro for at least some strains of beta-hemolytic streptococci and to a less degree for some other organisms; they found Prontosil Soluble without bacteriostatic activity in vitro. Later Bliss and Long⁴ found Prontosil Soluble after reduction with cysteine hydrochloride to be bacteriostatic in vitro. Attempts to demonstrate a bacteriostatic activity of the blood of patients after treatment with these products are open to question because of the bactericidal effect of serum from patients with hemolytic streptococcus infection.⁷

Since the therapeutic activity of Sulfanilamide seems to be dependent on its presence in adequate concentration in the blood, the rational method of treatment, and the one that has yielded good results in the cases reported, is the administration of relatively large initial doses followed by smaller doses sufficient to maintain an adequate level of the drug in the blood of the patient over a considerable length of time. Long and Bliss⁸ regard 10 mg. of Sulfanilamide per hundred cubic centimeters of blood as a satisfactory level. Marshall, Emerson and Cutting⁹ have described a rapid method for determining

1. It is unfortunate that the term "Prontosil" is used in this country for a compound not identical with the product which has been sold in Europe under the same name. This leads to much confusion in the medical literature.

the Sulfanilamide in the blood and urine, thus affording a means of controlling the dosage so as to maintain a desired concentration of the drug in the blood. That it may be important to do so is illustrated by a case in which there was failure to respond satisfactorily to Sulfanilamide given orally. Analysis of the blood showed that only small amounts of the drug were being absorbed. Therefore Sulfanilamide in physiologic solution of sodium chloride (0.8 Gm. of sulfanilamide powder in 100 cc. of physiologic solution of sodium chloride, heated to 90 C. until solution is effected, then cooled to 37 C. and used at that temperature) was injected subcutaneously and was followed by a prompt and satisfactory clinical response. There are probably differences in the rate of absorption of the drug from the gastro-intestinal tract by different individuals.

Either Prontosil Soluble or Sulfanilamide is quite rapidly absorbed. Colebrook and Kenny¹⁰ came to the conclusion that there is little or no reason for injecting the drugs intravenously. Marshall, Emerson and Cutting⁹ found that "in dogs, the concentration in the blood does not mount more quickly or attain a higher level with subcutaneous administration [of Sulfanilamide] than with oral." The only occasion for parenteral administration would seem to be in those cases in which oral administration is impracticable. It may also be advisable to use the parenteral route for at least a part of the drug when large doses are being given and when nausea may be produced by oral administration.

Long and Bliss¹¹ have employed during the first twenty-four hours of treatment maximum doses of 120 cc. of Prontosil Soluble (2.5 per cent solution) (1 cc. for each pound of body weight) or 5 Gm. of Sulfanilamide (1 Gm. for each 20 pounds, or 9 Kg., of body weight) and when Prontosil Soluble was used parenterally and Sulfanilamide orally the total dose has been correspondingly divided between the two products. They found such doses effective, although some clinicians have used larger doses¹² and Colebrook and Kenny¹⁰ employed smaller doses. It should be noted that theoretically 100 cc. of Prontosil Soluble (2.5 per cent solution) should yield only 0.73 Gm. of Sulfanilamide if completely and quantitatively broken down. A great disproportion in the amounts of these two drugs recommended is therefore obvious. More exact clinical and experimental data are required to determine the therapeutic equivalence of the drugs.

When given in the doses mentioned, the immediate toxic effects of the drugs have not been particularly alarming but as with the use of any drug, especially when new, caution in administration is necessary. A variable degree of transient nausea sometimes accompanies the oral administration of Sulfanilamide and it may be necessary in some cases to inject a properly prepared solution of Sulfanilamide (powder), or Prontosil Soluble. Probably a certain degree of acidosis occurs in all patients receiving the drugs.¹³ Many cases of cyanosis occasionally associated with sulfhemoglobinemia have been observed. The association of this condition with saline cathartics is not fully established. Rarely jaundice may occur. Pyrexia also frequently occurs and it is important "to differentiate between fever produced by the infection and fever produced by the chemical."¹¹ There have been unreported cases of acute hemolytic anemia and agranulocytosis in cases treated with Sulfanilamide, although the relation of the drug to these conditions was not fully established. Marshall, Emerson and Cutting⁹ state that "In patients with impaired renal function, the sulfonamide appears to be excreted more slowly. Until more data are available it should be given with care in all cases of renal insufficiency." The toxic effects of prolonged administration of the drug are unknown. Long and Bliss¹¹ reported recurrence of hemolytic streptococcus infection in mice after apparent recovery and as late as sixty days after the administration of Prontosil Soluble had been discontinued. Since mice are much more susceptible to virulent hemolytic streptococci than is man, the survival of very few of these organisms might be expected to bring about such a result. Even though such occurrences may be less frequent in human

patients, it would appear inadvisable to discontinue treatment too soon. The patient should be kept under observation and treatment restored on any evidence of recurrence of the infection.

There is rapidly increasing evidence that Sulfanilamide and its derivatives are useful therapeutic agents in the treatment of infections with beta-hemolytic streptococci, both local and generalized. A bibliography of published reports will be found in the article by Long and Bliss.¹¹ It must be borne in mind that there are many different kinds of beta-hemolytic streptococci. Lancefield¹⁴ and Hare¹⁵ recognize nine serologic "groups," and each of these groups may be serologically subdivided into several "types." The hemolytic streptococci causing most of the acute and severe infections in man belong to group A. It is with the streptococci of this group that the reported experiments in mice and in vitro have been done. Undoubtedly most of the human cases treated were infections with group A streptococci. Certain members of group B, C, D, F and G have also been found in human infections, although most strains of these groups are probably rightly regarded as nonpathogenic for man. Colebrook and Kenny¹⁰ report one case of group B infection successfully treated and one case of group G infection unsuccessfully treated. Long and Bliss¹¹ report the treatment of one case of group B infection in which a relapse occurred one week after discontinuance of Prontosil Soluble administration. It is highly desirable that in the study of the treatment of more cases adequate bacteriologic studies be reported. This is further emphasized by the observations that the treatment of mice infected with hemolytic streptococci of low mouse virulence was unsuccessful.¹⁶ No success has been reported for the treatment of infections due to alpha and nonhemolytic streptococci. Proom¹⁷ reports the protection with Sulfanilamide of mice infected with meningococci. At the time of the preparation of this report there were certain unpublished reports of the usefulness of the drug in cases of human infection with meningococci, gonococci and certain types of pneumococci. Some of these have since been published.¹⁸

Since there is adequate evidence that Sulfanilamide is an effective drug for the treatment of grave hemolytic streptococcus infections which are often fatal, its use for such cases appears to be justified although the ultimate toxic effects of the drug are not yet fully known. It is important, however, that it should not be used indiscriminately. It is not a panacea. Whenever possible its use should be determined by adequate bacteriologic diagnosis. If in practice it is sometimes impracticable to obtain bacteriologic diagnosis before beginning treatment and the patient is acutely ill with what appears clinically to be a hemolytic streptococcus infection, initiation of treatment may be justified but, until more is known of the untoward effects of the drug, treatment should probably be discontinued if the infection proves to be due to other than hemolytic streptococci.

CONCLUSIONS

The original Prontosil (hydrochloride of 4-sulfamido-2':4'-diaminoazobenzene) is not considered. Although this is the original product investigated and found to be of therapeutic value, it is not being promoted because Prontosil Soluble and Sulfanilamide are considered to be superior products.

It seems doubtful whether the Winthrop Chemical Company is justified in using the name "Prontosil" for Prontosil Soluble (disodium salt of 4-sulfamido-phenyl-2'-azo-7'-acetyl-amino-1'-hydroxynaphthalene-3':6'-di-sulfonic acid), since the name has already been used for the previously named compound. It may be granted that Prontosil Soluble (2.5 per cent solution) has been shown to be therapeutically useful in many hemolytic streptococcus infections, but apparently it has no demonstrated

advantage over Sulfanilamide except in the matter of stability in solution and availability in ampules. It is promoted for parenteral administration only. The advantage of greater solubility would seem to be discounted by the fact that a 2.5 per cent solution is theoretically equivalent to a 0.73 per cent solution of Sulfanilamide. However, at 37 C. it would be possible to prepare a more concentrated solution of Prontosil Soluble and at lower temperatures the 2.5 per cent solution remains stable. Although in the therapeutic results reported it has generally been administered in less than this equivalent amount, it has not been shown by carefully controlled experiments that when given in less than equivalent amounts it is as effective as Sulfanilamide given in greater than equivalent amounts. Neither has it been shown that Prontosil Soluble, if given in amounts equivalent to the usual doses of Sulfanilamide, would not be more toxic than the latter. It has the disadvantage of coloring the tissues red.

Sulfanilamide (para-amino-benzene-sulfonamide) is apparently the active principle of the compounds just mentioned. It is colorless, relatively inexpensive and can be administered parenterally or orally. It has the apparent disadvantage of being relatively insoluble (0.8 per cent at 37 C. and 0.4 per cent at 15 C.) and, because of its tendency to crystallize out of solutions, has not been made available in prepared solution ready for injection. It is marketed in the form of tablets containing 0.3 Gm. and 0.5 Gm. of the drug mixed with an excipient and as Sulfanilamide powder. The tablets are not suitable for dissolving in solution for parenteral injection. For such purpose the Sulfanilamide powder should be used.

The Council voted to accept Sulfanilamide for inclusion in New and Nonofficial Remedies as a therapeutic agent for the treatment of infections by hemolytic streptococci of Lancefield's serologic group A. The Council will proceed with determining the acceptability of the various brands that have been submitted.

Council on Foods

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT.
FRANKLIN C. BING, Secretary.

ANNUAL MEETING OF THE COUNCIL ON FOODS

The annual meeting of the Council on Foods was held in the Association headquarters on March 11, 1937. Those present were:

Dr. F. C. Bing	Dr. G. F. Powers
Dr. Joseph Brennemann	Dr. J. S. McLester
Dr. Morris Fishbein	Dr. Mary Swartz Rose
Dr. P. C. Jeans	Dr. Russell M. Wilder
Dr. Howard B. Lewis	

Dr. Fishbein was reelected Chairman of the Council, and Dr. Jeans Vice Chairman.

A number of topics were discussed during the meeting which may be of interest to physicians, manufacturers and the general public.

The Book "Accepted Foods."—The Council discussed at some length the proposed book on accepted foods. A classification of the subject matter into chapters and these into sections was made and members of the Council were assigned to act as referees for each section.

Special Mixtures for Feeding Infants.—The referee of the Council presented a report on infant feeding preparations of the so-called one-formula type. The history of the development of this type of preparation was reviewed briefly. In the old days when it was difficult to feed a baby, an ideal food was wanted, one that would be as successful as human milk. A number of preparations were developed and in the hands of skilful pediatricians these met with more or less success; but it has been only within recent years, as our knowledge of nutrition increased, that more generally useful preparations were made commercially. The referee pointed out that it would be advantageous to practitioners if the composition of each accepted product was declared prominently on the label.

The number of units of vitamin D, for example, in products which contain this vitamin, should be declared together with a statement of the source of the vitamin. The Council voted that firms producing accepted mixtures for use in infant feeding be requested to declare on the labels the unitage and source of the vitamin D, if claims are made for the presence of this factor. Firms will be given, of course, ample opportunity to use up current labels.

The Nutritional Value of the Proteins in Milk.—A number of firms which produce cow's milk preparations for use in infant feeding have directed attention in their advertising to the nutritional value of the proteins of cow's milk as compared with human milk. The referee reviewed the most recent work on the nutritive value of the proteins of milk. These proteins consist principally of casein and lactalbumin, with small amounts of lactoglobulin and traces of one or two other proteins. Animal experiments indicate that the limiting factors in the nutritional value of casein and lactalbumin, the two most important proteins of milk, are the sulfur containing amino acids cystine and methionine. Casein contains less cystine but more methionine than lactalbumin. Because these two amino acids have almost equivalent nutritional value it would appear that, contrary to what has hitherto been supposed, casein is not inferior to lactalbumin. However, a more exact evaluation of the relative nutritive value of these two proteins cannot be made until more detailed information is available.

Sugars for Use in Infant Feeding.—The carbohydrate preparations that may be used in the artificial feeding of infants may conveniently be divided into three groups: pure sugars, hydrolyzed starch preparations, and mixtures. The referee reviewed the evidence regarding the nutritional value of each group in the feeding of infants. The claims that are made for the individual accepted products were discussed. It was the consensus of the Council that, in the light of available evidence, the choice of a sugar for use in infant feeding is of relatively minor importance as compared with other problems of infant feeding. Individual cases, however, might well require the selection of one sugar over another, but this, of course, is a matter for the practicing physician to decide.

What Amounts of Various Dietary Constituents Should Be Considered Significant.—The Council discussed the problem of rating individual food products as sources of the dietary essentials. The reports of assays and of chemical analyses should be interpreted in terms of human requirements. The referee brought out that a food can be regarded as a significant source of a dietary essential if it fulfils several tentative requirements:

1. In general, when one tenth of the day's requirement for an average man is furnished in a portion which can be easily eaten in one day, the food may be regarded as a "fair" source.
2. When one tenth of the day's requirement is contributed by an amount of the food which at the same time furnishes not more than 200 calories, the food may be classed as a "good" source.
3. When one tenth of the day's requirement is furnished by a food which appears in the diet practically every day, and in which the portion contributing one tenth of the essential furnishes not more than 100 calories, the food may be classed as "excellent."
4. When a food is not one which can be easily eaten in amounts to furnish one tenth of the day's requirement, or is one eaten infrequently, or both, and the amount required for one tenth of the day's allowance of the essential furnishes more than 200 calories, the food is a negligible or poor source.

It was brought out that a number of additional factors should be considered. Not all the calcium or the iron of foods may be available. Foods in general are relatively poor sources of vitamin D. In the final analysis, the rating of foods as excellent, good, fair, poor or negligible sources of the different essentials of the diet is a matter of judgment. It was the consensus of the Council that this subject should be discussed in the form of a report and that a table of allowable claims for various foods should be prepared as a guide for interested persons.

Vegetable and Fruit Juices.—The referee mentioned that while there are individual differences in the fruit juices, both fresh and canned, they can well be considered as a class. They are valuable foods and have a fairly well defined place in the diet. But their value sometimes is grossly exaggerated. The claim that fruit juices will prevent or cure colds has no basis in fact. There is no clear-cut evidence that any one brand of fruit juice is significant in the prevention of dental caries. From a nutritional standpoint, the chief value of fruit juices lies in their content of vitamin C and, to a less extent, vitamins B₁ and A. An important component is their water content; by drinking fruit juices, a sick person and, indeed, a well person, can be induced to take larger amounts of water. The carbohydrate content of fruit juices is a factor to be considered, also, especially in diabetes.

The Problem of Lead in Foods.—Lead is a toxic cumulative substance which usually gets into the body from sources other than foods. Available evidence indicates that natural food products contain minute traces of this metal. Some fruits and vegetables may become contaminated with spray residues which contain lead; special methods of washing these foods should be observed by growers. Food products may become contaminated with lead during manufacture unless simple precautionary measures are observed. There is no evidence that the products which stand accepted by the Council contain harmful amounts of lead. In the light of present day evidence the precautions suggested by the United States Department of Agriculture appear adequate, if enforced, to protect the public from ingesting harmful amounts of lead in food, and it appears that there is no cause for alarm. On the other hand, the Council believes that manufacturers should be cognizant of the problem in order that they may bend all efforts to avoid contamination of food products with lead during manufacturing processes.

The Policy of the Council Regarding the Fortification of Ordinary Foods with Vitamin D.—As a result of the recent Council decision not to accept any ordinary foods, other than milk, when fortified with vitamin D, the question was raised about the policy of the Council toward chocolate milk drinks so fortified. Chocolate milk drinks usually are prepared from milk which has had part of the cream removed. It appears that the addition of vitamin D to those products of this class, which are otherwise acceptable, might improve their nutritional value and apparently would not be contrary to the existing decisions of the Council. It was decided that further evidence of the suitability of chocolate milk drinks as a vehicle for providing the public with an additional source of vitamin D would need to be studied before the Council could arrive at a decision on this question.

There was also considerable discussion on the policy of the Council not to recognize ordinary cereal products fortified with vitamin D. One notion which has appeared in some of the scientific literature is that cereals contain a decalcifying substance the effects of which should be overcome by the addition of vitamin D. It was the opinion of the Council that there is no evidence that a toxic factor of this type exists and, therefore, there is no need of adding vitamin D to cereal products in order to overcome its alleged harmful effects. In general, cereal products are good, wholesome foods. Whether or not they possess special merit as a vehicle for carrying vitamin D is another question. From the information that is available to the Council, it seems that the possibility of adding vitamin D to cereal products is so restricted that only a few products containing significant amounts of vitamin D would be available to the public. The addition of vitamin D to cereal products undoubtedly would improve their nutritive values to the extent to which the vitamin D is added. However, it is not desirable to manipulate every food product so that it contains all the essentials needed for an adequate diet. The Council voted that, for the present, its policy not to recognize the fortification of ordinary foods other than milk with vitamin D should be continued.

Educational Advertising.—The referee brought up the question of the policy of the Council with regard to educational advertising. Leaflets, booklets and brochures are being prepared by many firms and widely distributed, especially in the schools. The Council has devoted considerable attention to

the nutritional claims made in general advertising material of this type. Many of the commercial pamphlets are well printed, handsomely illustrated and attractive. If carefully scrutinized, they are often of considerable value. The Council is more or less obligated, in the interests of the public and the medical profession, to review such material and to pass on it. The Council voted that the consideration of this type of advertising should be continued as in the past.

Scope.—The Council discussed two questions regarding its scope. It recently was voted no longer to accept, among other foods, ice cream and candy. After giving consideration to the factors involved, the Council voted again that candy products should not be considered for acceptance unless health claims are made for them. Some time ago the Council decided that ice cream and related products should not be continued on the list of accepted foods after June 1, 1937. This action was taken only because the facilities of the Council would not permit the consideration of individual products and is without prejudice to the products themselves. A number of manufacturers are considering the possibility of forming their own organization for the inspection and control of ice cream products. The Council believes that all manufacturers should be encouraged to raise the standards of their product. Whether or not the Council could recognize ice cream manufactured with special methods was not decided; judgment was withheld until future developments might afford greater opportunity for action in the interest of the public.

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COUNCIL ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION AND WILL BE LISTED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED.

FRANKLIN C. BING, Secretary.

FOUR BBBB "FRESHLIKE" BRAND STRAINED
UNSEASONED PRODUCTS (PEAS, BEETS,
CARROTS, SPINACH, GREEN BEANS,
TOMATOES, CELERY, APPLES,
PRUNES, APRICOTS, AND
VEGETABLES WITH
CEREAL AND BEEF
BROTH)

Distributor.—John Blaul's Sons Company, Cedar Rapids, Iowa.

Packer.—The Larsen Company, Green Bay, Wis.

Description.—Respectively strained peas, spinach, carrots, beets, green beans, celery, tomatoes, prunes, apples, apricots and vegetables with cereal and beef broth; prepared by efficient methods for retention in high degree of the natural mineral and vitamin values. No added sugar or salt. These products are the same as the respective accepted Larsen's vegetables and fruits (THE JOURNAL, Aug. 26, 1933, p. 675; Aug. 12, 1933, p. 525; Aug. 19, 1933, p. 605; July 8, 1933, p. 125; July 29, 1933, p. 366; Sept. 2, 1933, p. 779; July 1, 1933, p. 35; July 22, 1933, p. 282; Aug. 10, 1935, p. 437; July 4, 1936, p. 38; July 22, 1933, p. 283).

SEXTON BRAND YELLOW CLING PEACHES,
JUICE PACKED

Manufacturer.—John Sexton & Company, Chicago.

Description.—Canned peaches, packed in juice.

Manufacturer.—Yellow cling peaches fully tree ripened are halved, pits removed, mechanically peeled with caustic soda solution, spray washed under pressure, blanched, chilled and filled into cans. The cans are automatically filled with fruit juice, exhausted, sealed and processed.

Analysis (submitted by manufacturer).—(Analysis of entire contents including liquid): moisture 89.0%, total solids 11.0%, ash 0.5%, fat (ether extract) trace, protein (N \times 6.25) 0.5%, crude fiber 0.2%, carbohydrates other than crude fiber (by difference) 9.8%.

Calories.—0.41 per gram; 12 per ounce.

Claims of Manufacturer.—For diets in which sweetened fruit is proscribed.

SATURDAY, MAY 29, 1937

METABOLISM IN PREGNANCY

The ability of the body to deposit material in the tissues in times of plenty and to mobilize it when need arises can readily be demonstrated. Thus the areolar connective tissue is a reservoir for excess energy in the form of fat, the muscle and liver contain protein that is available in an emergency, and now even the skeleton is looked on as a labile structure as far as the give and take of mineral salts is concerned. It is not surprising, then, that metabolic balance studies tend to show differences in the retention of biochemically important substances depending on the relative adequacy of the intake of these substances before the period of observation. In general, a more or less prolonged suboptimal consumption of a dietary essential is likely to be followed by an increased retention when the supply is abundant. This phenomenon has been shown for nitrogen, vitamin A, calcium and cevitamic acid. There is now evidence indicating that previous environment (chiefly nutritional) may influence the accentuated exchange of metabolites during the reproductive cycle.

Pregnancy, from the point of view of physiologic economy, is a period of material gain to the maternal organism. Lactation is known to represent losses of considerable magnitude, due primarily to the removal of the milk. When, however, continuous balance studies are carried out through a large part of the periods of pregnancy and lactation, it becomes obvious that, under favorable nutritive conditions, large enough quantities of materials are probably stored during pregnancy to cover the losses incident to parturition and lactation. In a study of this kind on a human subject reported from the Children's Fund of Michigan,¹ emphasis was laid on the superior diet consumed during the period of observation. In a more recent study, Hummel and her co-workers² have recorded the daily

retention of nitrogen and several of the inorganic elements over the last sixty-five days of pregnancy in a primipara whose medical history over the previous six years showed an unsatisfactory nutritional background. The data were compared with those obtained under similar circumstances on a healthy woman (a quadripara). Of particular interest is the difference in retention of calcium and nitrogen; with the liberal allowance of 32.2 mg. of calcium per kilogram of body weight, the primipara showed a mean daily retention of 13.2 mg., whereas the healthy control subject retained only 4.8 mg. daily on an intake of 40.8 mg. per kilogram of body weight. The mean total daily intake of nitrogen for the primipara and for the control was 14.05 and 19.03 Gm. respectively, whereas the storage was 1.32 and 3.02 Gm. Correlated with the smaller retention of nitrogen by the primipara was a considerably smaller production of milk. Furthermore, it was shown that only during the latter half of the period of observation were the needs of the fetus for nitrogen met by that retained from the food in this subject.

Circumstances other than gravidity appear to exert an influence on the retention of materials derived from the food during pregnancy. It is of considerable interest that the tendency to reestablish depleted stores was not changed by the gravid state as far as calcium is concerned in this study. The foregoing evidence indicates that, despite the ordinarily effective biochemical devices whereby the organism insures against maternal loss as a result of the reproductive cycle, the maintenance of a favorable physiologic and nutritional background at other times is an important safeguard for the metabolism of pregnancy.

PHYSICAL "FITNESS" AND IMMUNITY TO PNEUMOCOCCI

The effects of the metabolic rate on the immune reactions of the body are significant from the points of view of both etiology and treatment. As a first step in such an investigation Locke¹ determined the metabolic efficiency of rabbits. Stock animals were chilled by partial immersion in cold water until the rectal temperature had been reduced to approximately 95 F. The rabbits were then dried with absorbent cloths and the speed of return to normal temperature was noted. In the most efficient rabbits a 3 degree rise in rectal temperature occurred within twenty minutes. Rabbits requiring forty minutes for a similar rise were rated lower, while those requiring as long as 125 minutes were placed in still another group. Ratings were fairly constant for each animal.

Several rabbits of each group were selected for immunologic tests. Each rabbit was injected intravenously with from six to eighty-three virulent type I pneumococci per cubic centimeter of calculated blood volume. Blood cultures (pour plates) were made at

1. Hunscher, Helen A.; Hummel, Frances C.; Erickson, Betty N., and Macy, Icie G.: *J. Nutrition* 10: 579 (Dec.) 1935. Hummel, Frances C.; Sternberger, Helen R.; Hunscher, Helen A., and Macy, Icie G., *ibid.* 11: 235 (March) 1936.
2. Hummel, Frances C.; Hunscher, Helen A.; Bates, Mary F.; Bonner, Priscilla; Macy, Icie G., and Johnston, J. A.: *J. Nutrition* 13: 263 (March) 1937.

1. Locke, Arthur: *J. Infect. Dis.* 60: 106 (Jan.-Feb.) 1937

the end of thirty minutes, one hour and three hours to determine the rate of disappearance of the pneumococci from the circulation. The blood of all rabbits of the first group was free from organisms within thirty to sixty minutes, even after intravenous doses as high as eighty-three micro-organisms per cubic centimeter. Ninety-two per cent of the rabbits of this class showed no fever or other demonstrable symptoms and all recovered from the infection. The rabbits of the last group, however—those without efficient heat regulation—were unable to remove pneumococci from the circulation even when the intravenous dose was reduced to six micro-organisms per cubic centimeter. All these rabbits died within three days of pneumococcal septicemia. The rabbits of the intermediate group varied in becoming bacteria free and in recovery.

In a second series, Locke observed the penetration into the blood stream of pneumococci derived from artificially produced intradermal foci. The results were obtained from plates poured at the end of twenty-six hours. Sixty-nine per cent of the most efficient rabbits showed negative blood cultures at this time. Most of them recovered from the infection. The third group of rabbits showed a count of 2,000 or more pneumococci per cubic centimeter of blood at the end of twenty-six hours. All these animals died from the resulting generalized infection. As before, rabbits of the second group occupied an intermediate position.

Improvements in the rating of all groups were observed following transfer of the rabbits to quarters 20 degrees F. cooler. Morphine administered in doses sufficient to inhibit shivering decreased the fitness ratings, smaller doses being without immunologic effects. Significant decreases were observed also following withdrawal of food. Occasional improvement was noted following subcutaneous injection of "antuitrin." Improvements also followed intravenous injection with adrenal cortex extract. Daily feeding with liver extract prepared for the treatment of pernicious anemia (or an intravenous injection with smaller doses of this extract) led in all cases to improvement. Control intravenous injections with peptone, heparin or normal horse serum were negative.

In order to determine the possible clinical applications of his "physiologic gradient," Locke measured the oxygen consumption and body surfaces of sixty-eight persons during maximum effort. Oxygen consumption varied from 410 to 1,500 cc. per minute for each square meter of body surface. Relative fitness was calculated by arbitrarily assigning a fitness rating of 1 (100 per cent) to the highest figure (1,500 cc.). Thus, a person consuming 410 cc. of oxygen per minute would have a calculated rating of $\frac{410}{1,500}$, or 0.27. The sixty-eight persons thus classified on the basis of respiratory efficiency were asked to report the number of colds they had had during the observation period of seven months. Eighteen persons with fitness ratings above 0.6 reported one cold or less during this period. Nine persons with

fitness ratings below 0.5 reported four colds or more during the same period. These observations are suggestive, but their exact clinical significance obviously awaits further investigation.

THE EXCHANGE OF SALT AND WATER BETWEEN MUSCLE AND BLOOD

"The composition of tissue cells cannot, like that of blood cells, be determined by direct analysis, because these cells cannot be separated from the interstitial substance which surrounds and connects them. The existence of the latter cannot be questioned; its volume and character defy direct measurement." So writes Peters¹ in a comprehensive survey of the exchange of fluids in the body of man. The question as to whether clinical edema represents an increase in the volume of cells or of interstitial tissue fluids or of both has been the subject of some controversy in the past. While the interchanges of fluid and electrolytes that take place between the red blood cells and the plasma are now well described, the limitations mentioned by Peters have prevented any such precise description of similar exchange between the blood and the tissue cells.

By an ingenious combination of analysis and calculation, Eichelberger and Hastings² have thrown much light on the fundamental processes involved in the exchange of salt and water between muscle and blood. Their experiments were of necessity conducted in living animals, since they found that excised muscle quickly undergoes changes in permeability which destroy the physiologic meaning of observations on such tissues *in vitro*. They found that normal muscle, calculated on a fat-free basis, consists of about 17 per cent of interstitial fluid, by weight, and about 83 per cent of cells. The water content of the whole muscle averages 76.5 per cent and of the cells 71.7 per cent, the variations from the average being hardly greater than in the case of serum. That muscle cells contain little or no sodium or chloride had previously been suspected; their observations leave little doubt that this is the case and that the cells must be considered impermeable to these ions as well as to those of potassium.

Of special interest is their demonstration that simple fluid excess, uncomplicated by acidosis or alkalosis, results in an increase in the intercellular fluids without either swelling or shrinkage of the cells. Some swelling of the cells occurs when alkalosis is induced by overbreathing, while acidosis induced by rebreathing of expired air results in shrinkage of the cells. It is noteworthy, however, that except under extremely abnormal conditions the changes in volume observed, either of

2. Hastings, A. B., and Eichelberger, Lillian: The Exchange of Salt and Water Between Muscle and Blood: I. The Effect of an Increase in Total Body Water Produced by the Intravenous Injection of Isotonic Salt Solutions, *J. Biol. Chem.* **117**: 73 (Jan.) 1937. Eichelberger, Lillian, and Hastings, A. B.: II. The Effect of Respiratory Alkalosis and Acidosis Induced by Overbreathing and Rebreathing, *ibid.* **118**: 197 (March) 1937; III. The Effect of Dehydration, *ibid.* **118**: 205 (March) 1937.

the cells or of the interstitial fluids, were relatively small. These results would appear to cast doubt on the view that either acidosis or alkalosis is actively concerned with the occurrence of clinical edema.

PROGRESSIVE POSTOPERATIVE GANGRENE OF THE SKIN

Thomas S. Cullen¹ in 1924 described a case in which, following an operation for a deep seated abdominal abscess, there developed an excessive ulceration and necrosis of the abdominal wall. This was apparently the first case of the kind to be described. Since then, however, cases have been reported by Brewer and Meleney, Hellström, Kappis, Baker and Tarry, Horsley, Christopher and others. The condition presents a fairly typical clinical picture. The great majority of the cases developed following the drainage of a deep abscess, either in the peritoneal cavity or in the thoracic cavity. Liedberg² states in a recent review that appendicitis was the most frequent primary disease among the forty-one cases he had collected. In nineteen of the cases of appendicitis, drainage was instituted. Of the four cases involving the thoracic wall, three developed after an operation and drainage for empyema and one after incision and drainage of a breast abscess. The eight fatalities in this series were directly due to the progressive nature of the complication and not to the primary disease.

The symptoms begin to appear, as a rule, at the end of the first or second week after the operation. At first they suggest an infection either of the whole wound or of the areas about the skin sutures. The wound edges after a few days become purple, while the outer zone takes on a bright red discoloration, which gradually fades out into the normal skin. The process involves only the skin and the subcutaneous tissues and does not extend into the fascia or the musculature. The involved area is painful and exquisitely tender. The spread of the gangrenous process is slow but unremitting and may involve the entire surface of the abdominal wall and the chest wall or may spread to the thigh. The febrile reaction and the constitutional symptoms are mild but the unremitting character of the disease and the excruciating pain caused by the slightest manipulation of the wound bring about a psychic depression and a lowering of vital functions which may terminate in death.

Meleney,³ employing accurate bacteriologic methods, isolated from the periphery of an excised lesion a pure culture of a micro-aerophilic nonhemolytic streptococ-

cus. In the gangrenous tissue itself the organism was found to be associated with the hemolytic *Streptococcus aureus*. Meleney further found that if either of the organisms was injected into animals in a pure culture a lesion was not produced but that when the two were mixed and injected a gangrenous lesion similar to that seen in clinical cases resulted. Meleney advances the hypothesis that the disease is the result of a synergistic action of the two organisms, the nonhemolytic micro-aerophilic streptococcus being the essential organism in the zone of advance, in some way preparing the ground for the gangrenous action of the combined organisms. The streptococcus described by Meleney corresponds to the *Streptococcus evolutus* of Prévot.

Conservative therapeutic measures, such as the employment of the various disinfecting substances, the use of vaccines or arsphenamine, radiation therapy, blood transfusions or the excision of the gangrenous margins of the wound, have failed to check the progress of the disease. Radical excision of the entire involved area, however, including the outer red zone, proved to be effective. The patient is at once relieved of the intractable pain, the general condition rapidly improves and the denuded area responds favorably to skin transplants.

Current Comment

VITAMIN D MILK

The Council on Foods of the American Medical Association¹ has decided that for the present milk is the only common food that will be considered for acceptance when fortified with vitamin D. Hence the recent discussion by Krauss and Bethke² on new developments in the field of vitamin D milk is especially worthy of comment. Numerous methods, as they point out, are available for increasing the vitamin D content of milk. In attempting to evaluate the best method for the particular circumstances, factors aside from cost must be taken into consideration. Control, that is, the assurance that milk contains the specified amount of vitamin D, is of great importance. At present this control is vested in various groups of governmental agencies and differs widely, therefore, in adequacy. The importance of standardization of the procedures for fortifying the milk and the determination of the best agency for control is readily evident from the figures cited by these authors concerning present vitamin D consumption. They quote from the October 1936 issue of *Vitamin D Milk* as follows: "It is reliably estimated that, in the United States, vitamin D fluid milk is now being consumed at the rate of about 400,000,000 quarts annually. While this is only about 3 per cent of the total volume of household fluid milk, it really represents a very considerable amount of organization, made within a relatively short time. In

3. Meleney, F. L.: Differential Diagnosis Between Certain Types of Infectious Gangrene of the Skin, with Particular Reference to Hemolytic *Streptococcus Gangrene* and Bacterial Synergistic Gangrene, *Surg., Gynec. & Obst.* 56: 847 (May) 1933.

1. The Present Status of Vitamin D Milk, *J. A. M. A.* 108: 256 (Jan. 16) 1937.

2. Krauss, W. E., and Bethke, R. M.: New Developments in the Field of Vitamin D Milk, *Bull. Ohio Agricultural Experiment Station* 22: 154 (Jan.-Feb.) 1937.

addition, it is estimated that the yearly consumption of evaporated vitamin D milk is equivalent to 800,000,000 quarts of fluid milk. The consumption of both kinds is equivalent to over a billion quarts of fluid milk annually." While these are figures cited for the whole United States, there are others available which indicate tremendous variation in consumption among different communities. If vitamin D in milk is as important as some believe, this variation is unsatisfactory either because some communities are getting too little or others are getting more than they need. In Chicago, according to a report quoted in this paper, vitamin D fluid milk constituted about 6 per cent of all fluid milk sold during the period from June 1934 to June 1935. For Elizabeth, N. J., from 2 to 3 per cent of all fluid milk entering that city during the early part of 1936 was vitamin D milk. According to data received in July 1936, Portland, Maine, tops all other cities in the use of vitamin D milk, with about 19 per cent of all the fluid milk consumed there being fortified with vitamin D. It is thus obvious that much work remains to be done in determining the needs of communities for vitamin D milk, the preferred methods of adding the vitamin D to the milk, and its careful control to assure satisfactory vitamin D content.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ALABAMA

Changes in the Faculty.—Dr. Philip B. Armstrong, assistant professor of anatomy at Cornell University Medical College, New York, has been appointed professor of anatomy at the University of Alabama School of Medicine to succeed Dr. Franklin S. DuBois, who has accepted a fellowship at the Mayo Foundation. Dr. Armstrong graduated from Cornell in 1926. Other changes are: Dr. Oscar O. Christianson, associate in pathology, Cook County Hospital, and instructor in pathology at Rush Medical College, Chicago, will succeed Dr. Cornelius S. Hagerty as assistant professor of bacteriology and pathology when he leaves at the end of the session to engage in private practice in Chicago. Dr. Ben Neely Miller has been appointed to succeed Dr. Wallace S. Marshall as instructor in physiologic chemistry. Dr. Marshall will enter the practice of medicine in Wisconsin with his father. Dr. John H. Ferguson, associate professor of physiology and pharmacology since 1935, will also leave at the end of the session to become assistant professor of pharmacology at the University of Michigan School of Medicine; his successor has not been announced. Dr. Herbert K. Fidler has been named assistant professor in bacteriology and pathology.

ARKANSAS

Personal.—Dr. Wylie R. Felts has been elected mayor of Judsonia. Dr. John B. Elders has been appointed medical director of health district number 12, with headquarters at Paragould. Dr. Allie C. Kolb has resigned as superintendent of the state hospital at Little Rock.

District Meetings.—Dr. Frederick H. Krock, Fort Smith, discussed "Treatment of Acute Infections of the Urinary Tract" before the Second Councilor District Medical Society, April 5, in Searcy, and Dr. Ralph E. Weddington, Fort Smith, "Nephritis in Childhood: Its Clinical Course and Management." The Third District Medical Society was addressed, April 6, in Clarendon, by Drs. Milton C. John Jr., Stuttgart, management of the menopause; Alan G. Cazort, Little Rock, "Allergy in General Practice"; Gilbert J. Levy, Memphis, Tenn., "Infantile Paralysis," and Lee Vallette Parmley, Little

Rock, "Brain Trauma."—The First Councilor District Medical Society met in Blytheville, May 4, with the following speakers, among others: Drs. Robert Lyle Motley, Memphis, Tenn., "Treatment of Edema, Cardiac and Renal"; Ellis Fischel, St. Louis, "Treatment of Cancer," and Chester D. Allen, Memphis, Tenn., "Urinary Infections."

COLORADO

Society News.—Dr. Vernon G. Jeurink, Denver, addressed the Northeast Colorado Medical Society, April 6, on common problems of proctology.—Dr. Albert Bessemans, rector, Ghent University of Belgium, addressed the faculty of the University of Colorado School of Medicine, Denver, and the Medical Society of the City and County of Denver, May 5, on "Experimental Data on Antisyphilitic Hyperpyrexia Produced by Physical Agents."

CONNECTICUT

Society News.—Clarence C. Little, D.Sc., Bar Harbor, Maine, addressed the Yale Medical Society, New Haven, recently, on "A Comparison Between Genetics of Morphological Characters and Cancer of Mice." The society was addressed, April 14, by Drs. Milton C. Winternitz, Robert M. Thomas and Philip M. LeCompte, among others, on "Pathology of Arteriosclerosis." Dr. Albert Bessemans, rector of the University of Ghent, Belgium, addressed the society April 9 on "Antisyphilitic Hyperpyrexia Produced by Physical Means."—Dr. Edward J. Humphreys, director of research, Letchworth Village, Thiells, N. Y., addressed the New England Society of Psychiatry in Norwich, April 27, on "Present Day Research Trends in the Field of Human Deficiency."

Dr. Cushing Will Retire from Yale Faculty.—Dr. Harvey Cushing, since 1933 Sterling professor of neurology, Yale University School of Medicine, New Haven, will retire from the faculty in June, according to the New York Times. Dr. Cushing graduated from Harvard University Medical School in 1895. He was associated with Johns Hopkins University School of Medicine from 1902 to 1912 and from 1912 to 1932 was professor of surgery at Harvard and surgeon-in-chief to the Peter Bent Brigham Hospital. He engaged in the practice of surgery from 1895 to 1933, when he went to Yale. He has been president of the American College of Surgeons, American Neurological Association and the American Surgical Association. He was awarded the Charles Mickle fellowship of the University of Toronto in 1922, the Cameron Prize of the University of Edinburgh in 1924 and the Lister Medal in 1930. In 1925 he was awarded the Pulitzer Prize for his book "The Life of Sir William Osler."

ILLINOIS

Society News.—At a meeting of the Mercer County Medical Society, Aledo, April 13, Drs. Frederick H. Lamb, Davenport, Iowa, presented a paper on "Comparison of Defects in Various Types of Anemia" and Harold M. Camp, Monmouth, "The Eradication of Syphilis."—Dr. Walter C. Alvarez, Rochester, Minn., addressed the Vermilion County Medical Society in Danville, April 6, on "Diagnosis and Management of Some of the Commoner Gastro-Intestinal Tract Disorders."—Dr. Fred H. Albee, New York, discussed "Surgical Restoration of Lever at the Top of the Femur" before the McLean County Medical Society, April 15, in Bloomington.—Dr. Abraham A. Low, Chicago, discussed "Insulin Shock Therapy in the Treatment of Dementia Praecox" before the Kankakee County Medical Society, Kankakee, April 9; Dr. Robert R. Smith, then managing officer of the Kankakee State Hospital, was host to the society at a dinner preceding the lecture. The society was addressed at a special meeting, April 2, by Dr. Edwin S. Hamilton, Kankakee, on "The Future of the Practice of Medicine."

Chicago

University News.—Two new courses have been added to the curriculum of Loyola University School of Medicine. They are intended as a preparation for the study of psychiatry, psychobiology for the freshmen and psychopathology for sophomores.

Campaign Against Illegal Practitioners.—In the current drive against illegal practitioners by the state department of registration, Ali Mohamed, 714 East Forty-Third Street, was sentenced, April 19, to sixty days in the county jail for violation of the state medical practice act. Similar charges were placed against the following: F. L. Tener, chiropractor, 817 North Ashland Avenue, pleaded guilty, April 30, and fined \$100 and costs; Joseph J. Daily, also known as "Burt," 1007 South

State Street, room 55, pleaded guilty, April 29, and was sentenced to sixty days in the county jail; J. M. Gilmore, 5659 West North Avenue, pleaded guilty, April 28, and fined \$100 and costs; Carl R. Canfield, pharmacist, 7101 South Halstead Street, pleaded guilty, April 26, fined \$200 and placed on one year's probation. Others arrested in the roundup include:

William J. Carrington, 112 West Randolph Street.
Erling E. Saland, 3 West Madison Street, Oak Park, Ill.
Elmer Leroy Spencer, 13008 South Western Avenue, Blue Island.
James A. Craig, Box 142, Cook County, Robbins, Ill.
J. E. Bradley, Aero Laboratories, 1549 North Western Avenue.
Ali Yehi DeBeh, 2510 North Lincoln or 910 Sunnyside Avenue.
Dr. J. Nowak, 1200 North Ashland Avenue.
Erich Frankowsky, D.O., 4010 West Madison Street.
Otto C. Mollnauer, 3440 West Fullerton Avenue.
O. C. Moe, chiropractor, 3442 Fullerton Avenue.
F. W. Ackerman, 4026 North Kimball Avenue and 4009 Bernard Street.
R. A. Bercier, Tremont, Ind., and 2848 North Kedzie Avenue.
P. M. Hardesty, D.C., 3450 Irving Park Boulevard.
M. Koltunski, 1032 North Ashland Avenue.
Frank Paderevski, 202 South State Street.
Louis Marinakos, 1209 South Cicero Avenue, Cicero, Ill.
James Johnson, 3735 South State Street.

INDIANA

Society News.—The Tippecanoe County Medical Society, Lafayette, heard Dr. Archibald L. Hoyne, Chicago, discuss "Diagnosis and Treatment of Communicable Diseases," April 13.—Dr. George A. McDowell, Fort Wayne, addressed the Whitley County Medical Society in Columbia City, April 13, on "Obstetrics in the Home."—The St. Joseph County Medical Society was addressed at South Bend, May 19, by Dr. Samuel M. Feinberg, Chicago, on "Air-Borne Nonpathogenic Fungi: A Newly Recognized Menace to Allergic Individuals."—Dr. Louis J. Karnosh, Cleveland, discussed neurologic conditions in surgery before the Muncie Academy of Medicine, April 13, in Muncie.—At a meeting of the Rush County Medical Society, April 13, Dr. John R. Brayton, Indianapolis, discussed "The Diagnosis and Treatment of Early Syphilis."

Rehabilitation Program in Flood Area.—The four district health centers, temporarily established during the flood at Huntingburg, New Albany, Dillsboro and Evansville, will be maintained with health officers, sanitary engineers, public health nurses, supervisors and office personnel until the rehabilitation program is completed, according to a report of the state department of health in April. Most of the general health work was progressing satisfactorily and the largest part of the emergency sanitation work, such as pumping and slushing of wells, cisterns, water mains and similar activities, had been completed at the time of the report. Instruction sheets, pointing out principal public health hazards and offering suggestions, were printed under the supervision of the state board and tacked to houses. During the first four or five days, when the situation was most tense, it was necessary for the board to purchase and handle all medical supplies, although this is not regularly its function. About \$10,000 worth of medical supplies, exclusive of serums and vaccines, were rushed into the area. Hospitals in both the flood and refugee areas donated their facilities and staffs for service to the flood victims. Members of all county medical societies in the state responded with liberal donations, while those in the immediate flood areas cooperated by examining and inoculating refugees and victims without charge. At the request of the governor, a three day inspection tour of the stricken area was made. In Johnson County, 134 refugees were placed under quarantine because of one case of scarlet fever. In Evansville, the new American Legion headquarters was transformed into a sixty bed emergency hospital with a separate contagious disease ward to supplement the services of the regularly established hospitals. Newburgh cared for 197 patients during the first five days of the flood in the emergency hospital in the Masonic Lodge Hall and Red Cross Center, while the emergency hospital at Aurora, during the same period, treated 670 outpatients and thirty inpatients, according to the report, which is a general discussion and not a complete statistical analysis of the situation.

IOWA

Society News.—At a meeting of the Des Moines Academy of Medicine and the Polk County Medical Society, April 27, Drs. Dwight C. Wirtz and Dennis H. Kelly discussed "Elbow Fractures" and "Behavior and Habit Problems in Childhood" respectively. Drs. James L. Dubrow and Walter R. Wynne of the Veterans Administration Facilities addressed the society at a special scientific session, May 4, on "Primary Carcinoma of the Lungs."—Dr. Albert C. Moerke, Burlington, was elected president of the Iowa Society of Clinical Surgeons at its annual meeting in Iowa City, April 17.

Public Meeting on Venereal Diseases.—The Pottawattamie County Medical Society devoted its meeting in Council Bluffs, April 12, to a public meeting and open forum on the control of venereal disease. Dr. Ruben Nomland, professor of dermatology and syphilology, State University of Iowa College of Medicine, Iowa City, spoke on "The Nature and Dangers of Syphilis"; Dr. Marvin F. Haygood, deputy state health commissioner, Des Moines, "Present Status of Venereal Disease Control in Iowa," and Dr. William F. Snow, general director, American Social Hygiene Association, New York, "A Proposed Program for Venereal Disease Control."

LOUISIANA

State Medical Election.—Dr. Joseph A. O'Hara, New Orleans, was chosen president-elect of the Louisiana State Medical Society at its recent annual meeting in Monroe, and Dr. Charles M. Horton, Franklin, was installed as president. Vice presidents are Drs. Walter O. Moss, Lake Charles; Lionel J. Bienvenu, Opelousas, and Allen W. Martin, Bogalusa. Dr. Paul T. Talbot, New Orleans, was reelected secretary-treasurer. Dr. Hiram W. Kostmayer, New Orleans, the retiring president, was presented with a gold medal.

MAINE

Society News.—A recent meeting of the Cumberland County Medical Association was addressed by Dr. Walter Bauer, Boston, on gout.—Dr. George O. Cummings, Portland, discussed bronchocopy before the Portland Medical Society, April 6.—At a meeting of the Franklin County Medical Society, April 5, Dr. George L. Pratt, Farmington, read a paper entitled "The Medical Examiner System of Maine."—The Hancock County Medical Society was addressed in Ellsworth, April 21, in joint session with the dentists of the county; the speakers included S. Fred Briggs, D.D.S., Bangor, "Emotions and Their Relation to the Production of Dental Caries"; Dr. George F. Shurtleff, Swans Island, problems of the medical and dental professions, and Dr. Marcus A. Torrey, Ellsworth, "Sequelae Syndromes of the Eye, Ear, Nose and Throat from Primary Dental Origin."—A symposium on headaches was presented before the Kennebec County Medical Society, April 15, by Drs. Howard F. Hill, Waterville; Edwin R. Irgens, Waterville, and Clarence R. McLaughlin, Gardiner.—The Waldo County Medical Society was addressed in Belfast, May 19, by Dr. George F. Miller, Belfast, on "Angina Pectoris and Its Treatment."

MASSACHUSETTS

Dr. Madsen Gives the Cutter Lecture.—The Cutter Lecture on Preventive Medicine was presented by Dr. Thorvald Madsen, head of the State Serum Institute at Copenhagen and chairman of the Health Committee of the League of Nations, May 14, at Harvard University Medical School. His subject was "The Control of Syphilis in the Scandinavian Countries."

Personal.—Dr. Dwight O'Hara, professor of preventive medicine, Tufts College Medical School, has been appointed vice-dean, a newly created position, to supervise clinical instruction during the third and fourth years. He will continue with his duties as professor.—A banquet was held in honor of Dr. John J. Deacy, Lawrence, in celebration of his appointment as medical examiner of the Fifth Essex District. He was presented with a wrist watch. Those in attendance at the dinner included former Governor James M. Curley and Walter A. Griffin, mayor of Lawrence; Thomas F. Greene, D.D.S., was chairman of arrangements, and Attorney John P. Kane, toastmaster.

Health Director Appointed for Simmons College.—Dr. Helen L. Roberts, medical consultant at Simmons College, Boston, has been appointed to the faculty with the title of director of health and assistant professor of hygiene in accordance with an extended program of health service for students, effective in September. According to the New York Times under the new plan the director will have supervision of the two college infirmaries, treat cases of minor illness and recommend hospital care for the more serious cases, and will be responsible for the periodic examination of food handlers. A special fee will cover also five days of care each year in the infirmary if recommended by the physician. The college will not provide medicines, but it will assume the cost of laboratory tests and such vaccinations and inoculations as may be required. Any necessary x-ray work will be done at the college without additional expenses to the student other than for materials. Dr. Roberts, who will devote her full time to the needs of the

college community, graduated from the University of Michigan School of Medicine, Ann Arbor, in 1933.

Lectures on Obstetrics and Pediatrics.—Five lectures each on obstetrics and pediatrics were begun during April in Springfield, Fitchburg, Hyannis, Greenfield and Taunton, under the auspices of the Massachusetts Medical Society and the state department of health. The lectures are financed by social security funds and the speakers are:

- Drs. Delos J. Bristol Jr. and Robert L. DeNormandie, The Obstetric Examination.
- Drs. Marion F. Eades and Roy J. Heffernan, Delivery and the Puerperium.
- Drs. James C. Janney and Foster S. Kellogg, Bleeding in the Third Trimester.
- Drs. Herbert B. Nelson and Joseph W. O'Connor, The Toxemias.
- Drs. Louis E. Phaneuf, John Rock, Judson A. Smith and Raymond S. Titus, Sepsis.
- Drs. Warren R. Sisson and Richard S. Eustis, Nutrition Problems of Infants—Prevention and Treatment.
- Drs. Lewis W. Hill and Edward S. O'Keefe, Treatment of Common Skin Disorders in Infants and Children.
- Drs. Edwin H. Place and Conrad Wesselhoeft, Contagious Diseases with Special Reference to Prevention and Treatment.
- Drs. Richard M. Smith, Thomas H. Lanman, Joseph Garland and William E. Ladd, Abdominal Conditions in Childhood.
- Drs. Stewart H. Clifford and Robert N. Ganz, The Care of the New-Born and Premature Infant.

MICHIGAN

State Society Night.—The Lenawee County Medical Society and the Kalamazoo Academy of Medicine have designated June 15 and May 27, respectively, "state society night." These are the nights when officials of the Michigan State Medical Society are the guests of the societies.

Personal.—Dr. Robert L. Dixon, for seven years medical superintendent of the Michigan Home and Training School, Lapeer, has been appointed to a similar position at the Michigan Farm Colony at Wahjamega, a position he occupied in 1914, when the institution was established. At that time he resigned as state health officer of Michigan to accept the post, which he held until 1930, when he went to Lapeer. Dr. Dixon fills the vacancy left by the death of Dr. James T. Redwine. —Dr. Floyd J. Barkman, county physician of Menominee, has been appointed superintendent of the new Berrien County General Hospital, Berrien Springs. —Dr. S. Rudolph Light has been elected president of the Kalamazoo Chamber of Commerce.

Changes on the Faculty at Michigan.—Dr. Albert C. Furstenberg, dean and professor of otolaryngology, University of Michigan Medical School, Ann Arbor, has recently announced that Dr. Theron S. Hill, member of the staff of the State Psychopathic Hospital, has resigned, effective July 1, to accept an appointment to the department of neurology and psychiatry at Peiping Union Medical College, Peiping, China. The following promotions on the faculty of the medical school were also reported:

- Dr. Russell Nelson De Jong, to assistant professor of neurology.
- Dr. Ruth C. Wanstrom, to associate professor in the department of pathology.
- Dr. Walter Gierston Maddock, to associate professor of surgery.
- Dr. Norman R. Kretschmar, to associate professor of obstetrics and gynecology.
- Dr. Richard H. Freyberg, to assistant professor of medicine, department of internal medicine.
- Dr. John McFarland Sheldon, to assistant professor in the department of internal medicine.

MINNESOTA

Refresher Courses.—A series of lectures on obstetrics and pediatrics were to begin this month in Fulda, Brainerd, St. Cloud, Fergus Falls, Grand Rapids and Mankato, under the auspices of the state board of health cooperating with the state medical association and the extension division of the University of Minnesota. Members of the staff of the university will present the lectures, which will be financed by the social security funds.

Medal for Exhibit on Gallbladder.—Edward A. Boyden, Ph.D., professor of anatomy, University of Minnesota School of Medicine, Minneapolis, was awarded the gold medal for the best individual scientific exhibit at the annual meeting of the Minnesota State Medical Association in St. Paul, May 2-5. His subject was the gallbladder. The medal is awarded annually by the Southern Minnesota Medical Association. Honorable mention went to Dr. Lloyd F. Hawkinson, Brainerd, for his study on the endocrine glands, and to Dr. Horace Newhart, Minneapolis, for his exhibition on the prevention of deafness.

Hennepin County Meetings.—Karl W. Stenstrom, Ph.D., professor of biophysics, University of Minnesota, discussed the "Use and Misuse of X-Ray Therapy" before the Hennepin County Medical Society, Minneapolis, April 28. The society

was addressed by Dr. Edward L. Tuohy, Duluth, April 14, on "The Autopsy Protocol as a Key to Utilization of Current Medical Opinion and Research," and, April 21, by Drs. Ralph V. Ellis, Minneapolis, on "Specific Treatment of Hay Fever with Emphasis on Causes of Failure"; Horatio B. Sweetser, Jr., Minneapolis, "Multiple Sensitivity and Its Interpretation in the Allergic Patient," and Elmer M. Rusten, Minneapolis, "Allergic Skin Eruptions Due to Inhalant Factors."

MISSOURI

Hospital News.—A memorial plaque will be placed in the library of St. Anthony's Hospital, St. Louis, in honor of the late Dr. Harvey S. McKay, who was a member of the staff. It is also planned to maintain the library in his honor. —The newly erected Park Lane Memorial Hospital, St. Louis, was recently opened to the public. Dr. Frank J. Smith is superintendent.

Personal.—Dr. Malvern B. Clopton, Clarksville, has been appointed to a term of four years on the state board of health. —Dr. Rutherford B. H. Gradwohl has resigned as director of the laboratory and member of the pathology and bacteriology staffs of the St. Louis County Hospital; he has been succeeded by Dr. Hollis N. Allen. —Dr. Lon M. Tillman, Kansas City, has been appointed by Governor Lloyd C. Stark on the commission of nine to study the economic, industrial, education and civic needs of the Negroes of Missouri; he has been assigned to study the health aspect. —Dr. William P. Dysart, Columbia, has completed fifty years in the practice of medicine.

MONTANA

Personal.—Dr. Julio Raymond Soltero, Lewistown, has been appointed health officer of Fergus County, succeeding Dr. John C. Dunn, Lewistown, who has become head of the state hospital at Warm Springs.

Society News.—The Mount Powell Medical Society was addressed in Anaconda, April 30, by Drs. George W. Swift, Seattle, on "Diagnosis of Brain and Cord Tumor" and Walter A. Fansler, Minneapolis, "Carcinoma of the Rectum and Sigmoid." Dr. Swift also conducted a clinic in the afternoon. —The Montana Society of Internists was created at a recent meeting in Great Falls. Dr. Louis H. Fligman, Helena, was made chairman and Dr. Herbert C. Watts, Fort Harrison, secretary. An annual meeting will be held. —At a recent meeting of the Montana Academy of Oto-Ophthalmology, Dr. Arthur L. Weisgerber, Great Falls, was elected president, and Dr. Ashley W. Morse, Butte, was elected secretary.

NEW YORK

Alumni Clinical Day at Buffalo.—The Alumni Association of the University of Buffalo School of Medicine held its third annual clinical day April 17 at the Hotel Statler, Buffalo. During the day the following speakers addressed the meeting:

- Dr. Grover C. Penberthy, Detroit, Management and Treatment of Burns.
- Dr. Richard H. Jaffé, Chicago, Differential Diagnosis of Enlargement of the Lymph Nodes.
- Dr. Henry Page Mauck, Richmond, Va., Injuries Around the Knee Joint.
- Dr. Bernard Fantus, Chicago, Some Useful Prescriptions.
- Dr. Charles Gordon Heyd, New York, President, American Medical Association, Surgical Diseases of the Colon.
- Dr. Chevalier L. Jackson, Philadelphia, Bronchoscopy and Bronchography as Aids in the Diagnosis of Bronchopulmonary Disease.
- Dr. Hugh Cabot, Rochester, Minn., Management of Pyelonephritis.
- Dr. Heyd delivered an address at the annual dinner on "The Future of Medicine."

Dr. Ordway Resigns as Dean.—Dr. Thomas Ordway, since 1915 dean and professor of medicine, Albany Medical College, has resigned as dean, effective July 1, but will continue in his professorial capacity. His successor will be Dr. Robert Sydney Cunningham, professor of anatomy at Vanderbilt University School of Medicine, Nashville, Tenn., who will occupy a similar position at Albany together with his duties as dean. Dr. Ordway received his medical degree at Harvard in 1905 and was identified with the Boston City Hospital and Harvard University Medical School until 1909, when he was appointed director of the Bender Hygienic Laboratory, Albany, N. Y., becoming in the same year professor of pathology and bacteriology at Albany Medical College. In 1911 he returned to Boston as physician in charge of the Huntington Hospital at Harvard. He was appointed dean and professor at Albany in 1915. A native of Anderson, S. C., Dr. Cunningham graduated from Johns Hopkins University School of Medicine, Baltimore, in 1915. He joined the teaching staff of his alma mater in the same year, remaining there until 1925, when he resigned to become professor of anatomy at Vanderbilt.

Meeting of Proctologists.—The thirty-eighth annual meeting of the American Proctologic Society will be held in Atlantic City, N. J., June 6-8, with headquarters at the Marlborough-Blenheim. Among the features of the program will be symposiums on anesthesia and cancer of the rectum and colon. Speakers for the first will be Drs. Benjamin Haskell, Philadelphia; Joseph F. Saphir, New York, and Warren W. Green, Toledo, Ohio. For the second the speakers will be Drs. William H. Daniel, Los Angeles; George E. Binkley, New York; Edward G. Martin, Detroit; Robert A. Scarborough, San Francisco; Jerome M. Lynch and Georg Johnson Hamilton, New York. The society announces that admission to its meetings is now by invitation only.

American Heart Association.—The thirteenth annual meeting of the American Heart Association will be held at Hotel Haddon Hall, Atlantic City, N. J., June 7-8. Dr. Walter B. Cannon, Boston, will deliver the George Brown Memorial Lecture Monday afternoon on "Factors Affecting Vascular Tone." Other speakers on the program include:

Drs. Edgar V. Allen and Alfred W. Adson, Rochester, Minn., The Physiologic Effects of Extensive Sympathectomy for Essential Hypertension.
Dr. Burton E. Hamilton, Boston, Heart Disease in Pregnancy.
Dr. Wallace M. Yater, Washington, D. C., The Histopathologic Basis of Bundle-Branch Block.
Drs. Joseph B. Vander Veer and Robert F. Norris, Philadelphia, The Electrocardiographic Changes in Acute Pericarditis: A Clinical and Experimental Study.
Dr. J. C. Venno, of Quinidine Sulfate Intravenous.

Meeting on Rheumatic Diseases.—The American Association for the Study and Control of Rheumatic Diseases will hold its fourth annual meeting and sixth conference on rheumatic diseases Monday, June 7, at the Hotel Chalfonte-Haddon Hall, Atlantic City, under the presidency of Dr. Russell L. Cecil, New York. Among the speakers will be:

Dr. Cecil, The Necessity of Certain Criteria for the Diagnosis and Cure of Rheumatoid Arthritis.
Drs. Readie Garfield Snyder, Franz J. Lust, Cornelius H. Traeger and Le Moyne C. Kelly, New York, Gold Salts Therapy in Chronic Arthritis.
Dr. Edwin P. Jordan, Chicago, Critical Evaluation of Vaccine Therapy in Rheumatism.
Drs. Edward F. Bland and Thomas Duckett Jones, Boston, Fatal Rheumatic Fever.
Drs. Harry E. Thompson and Bernard L. Wyatt, Tucson, Ariz., Experimentally Induced Jaundice.
Dr. Philip S. Hench, Rochester, Minn., Further Observations of the Effect of Jaundice on Atrophic Arthritis and Fibrositis.

Session on Internal Secretions.—The twenty-first annual meeting of the Association for the Study of Internal Secretions will be held at Haddon Hall, Atlantic City, June 7-8, under the presidency of Dr. Francis M. Pottenger, Los Angeles. Included among the speakers will be:

Philip Bard, Ph.D., Baltimore, The Neural Basis of Estrual Behavior in the Cat.
Dr. Cyril N. H. Long, New Haven, Conn., The Mechanism of the "Diabetogenic" Action of the Pituitary.
Dr. Edgar Obermer, London, Thyroid Instability, Its Detection, Measurement and Treatment.
Dr. Roy G. Hoskins, Boston, Effects of Insulin on Cell Proliferation.
Dr. Daniel R. Mishell, Newark, N. J., Familial Intersexuality—A Report of Three Unusual Cases.
Frank A. Hartman, Ph.D., Columbus, Ohio, Certain Aspects of the Adrenal Cortex in Relation to Carbohydrates.
Dr. James B. Collip, Montreal, Further Studies on Anterior Lobe Hormones.

The annual dinner will be held Monday evening, when Dr. Pottenger will deliver his address and Dr. Levellys F. Barker, Baltimore, will discuss the "Progress of Endocrinology."

Meeting of Gastro-Enterologists.—The fortieth annual meeting of the American Gastro-Enterological Association will convene at the Hotel Claridge, Atlantic City, June 7-8, under the presidency of Dr. Chester M. Jones, Boston. The following, among others, will speak:

Dr. Louis E. Barron, New Haven, The Influence of the Extrinsic Innervation on the Human Gastric Motor Mechanism.
Drs. Harry Shay and Jacob Gerson-Cohen, Philadelphia, Experimental Studies in Gastric Physiology in Man.
Dr. Edward B. Benedict, Boston, Hemorrhagic Gastritis: A Gastroscopic Study.
Dr. Anton J. Carlson, Chicago, Studies on the Motility of the Colon.
Dr. Theodore A. Albansen, San Francisco, Deposition of Glycogen in Normal and Aged Livers After Oral and Intravenous.

Dr. Paul D. White, Boston, will deliver the Alvarez Lecture Monday on "The Differential Diagnosis of Cardiac and Gastro-Intestinal Disorders," and speakers at the annual dinner that evening will be Kirtley F. Mather, Ph.D., professor of geology at Harvard, on "A Geologist in Prophetic Mood," and Major Thomas Coulson, formerly of the British Military Intelligence Service, "Famous Women Spies."

Hospital Conference.—The first meeting of the Southeastern Hospital Conference, sponsored by the hospital associations of Alabama, Florida and Georgia, was held in Atlanta,

April 8-10. Mr. C. L. Sibley, superintendent, Birmingham Baptist Hospital, Birmingham, was chosen president of the conference for next year and it was decided to meet in Birmingham in April. Dr. Luther C. Fischer, Atlanta, was elected president of the Georgia Hospital Association, and Rev. Charles W. Curry, Savannah, secretary. Officers of the Florida Hospital Association include T. F. Alexander, Tampa, president, and Miss Gertrude Overstreet, Gainesville, president-elect. Officers of the Alabama association were not elected at this time. Speakers at the conference included Drs. John H. J. Upham, Columbus, Ohio, President-Elect of the American Medical Association; Bert W. Caldwell, Chicago, and Watson S. Rankin, Charlotte, N. C.

Academy of Tuberculosis Physicians.—The first scientific meeting of the American Academy of Tuberculosis Physicians, organized in 1936 during the annual session of the American Medical Association, will be held at the Hotel Dennis, Atlantic City, N. J., June 8. On the preliminary program are the following speakers, among others:

Dr. Max Pinner, Ithaca, N. Y., The Pathology of the Primary Tuberculous Complex.
Dr. Bruce H. Douglas, Detroit, The General Practitioner's Part in Controlling Tuberculosis in a Political Unit.
Dr. Charles O. Giese, Colorado Springs, Routine Treatment of Pulmonary Tuberculosis.
Dr. Chester A. Stewart, Minneapolis, Primary Tuberculous Infection Attack Rate.
Dr. Harry D. Lees, Philadelphia, The Earliest Manifestations of Pulmonary Tuberculosis in the Adult.
Dr. Edward W. Hayes, Monrovia, Calif., Dangers of Delay in Instituting Collapse Therapy in Pulmonary Tuberculosis.
Dr. Benjamin P. Potter, Secaucus, N. J., Bilateral Collapse Therapy.
Dr. Frank S. Dolley, Los Angeles, A Summary of the Results of Thoracoplasty.

Dr. Giese is president of the academy and Dr. Arnold Minnig, Denver, is secretary.

Guggenheim Fellowship Awards.—The John Simon Guggenheim Memorial Fellowships for 1937 include the following of medical interest:

Florence B. Seibert, Ph.D., professor of biochemistry, Henry Phipps Institute, University of Pennsylvania, Philadelphia, to study molecular sizes and cataphoretic mobilities of the active principle of tuberculin by means of the ultracentrifuge in the laboratory of Dr. Theodor Svedberg, University of Uppsala, Sweden.

James B. Sumner, Ph.D., professor of biochemistry, Cornell University Medical College, New York, to work also with the ultracentrifuge at Uppsala on determination of molecular weights of certain enzymes and crystalline proteins.

Eric G. Ball, Ph.D., associate in physiologic chemistry, Johns Hopkins University, Baltimore, to study mechanism of biologic oxidations at several European laboratories.

William Louis Straus Jr., Ph.D., associate in anatomy, Johns Hopkins, to study embryologic development of muscle function at the University of London.

Samuel R. M. Reynolds, Ph.D., assistant professor of physiology, Long Island College of Medicine, Brooklyn, to study the action of estrogen on uterine muscle at the University of Rochester.

Herbert Shapiro, research assistant in physiology at Princeton University, to investigate nerve activity at low oxygen pressure in studies at Plymouth, England, Naples and the University of London.

William Clouser Boyd, Ph.D., assistant professor of biochemistry, Boston University School of Medicine, to continue studies of blood groups among peoples in southwestern Asia.

Dr. Allan Lyle Grafflin, associate in anatomy, Harvard University, received a reappointment making possible continuation of study of the kidney.

FOREIGN

Yellow Fever Appears in Hongkong.—Two cases of yellow fever were reported in Hongkong, May 11, according to the Chicago Tribune. It has heretofore been unknown in Asia, the report stated.

Awards for Encephalitis Research.—The University of Bern, Switzerland, directs attention to its foundation to promote research in lethargic encephalitis. Prizes are awarded each year for work that shows real progress in the diagnosis or the treatment of the disease. The smallest prize amounts to about 1,000 Swiss francs. Applications should be sent to the dean of the medical faculty, which allocates the prizes at the end of the year.

Public Health Progress in Siam.—A new regimen of national hygiene is being attempted in Siam under the direction of Dr. Nai Young Huar, medical inspector of public health. Dr. Huar graduated from the University of Tennessee College of Medicine in 1924 and received a certificate of public health from Harvard School of Public Health in 1933. Dr. Huar is at present conducting a campaign to improve the dietary of the Siamese, urging them to eat a varied diet instead of a diet consisting mostly of rice. Siam has a plentiful supply of proteins and other foods, but because of ignorance and sometimes questionable ideas, the average inhabitant does not eat them. The budget for health service has been increased.

The Prevention of Maternal Mortality

The fact that while the general and the infant mortalities have been considerably diminishing the maternal mortality does not improve has exercised the government and the health authorities for some time. The Ministry of Health has had a special investigation into maternal mortality made by its medical officers, with the assistance of Sir Comyns Berkeley in a consultative capacity. For investigation forty-five areas were elected where maternal mortality has been more than 5 per thousand live births, twelve areas where it has more than the national average of 4, and twelve where it has been below the average. The object was to see whether careful examination of the circumstances attendant on deaths would indicate further measures, including matters of environment as well as treatment, which might be taken to reduce the mortality.

In a report that has just been published the investigators state that, though the total number of deaths due to child-bearing is relatively small (less than 8 per cent of the total deaths from all causes in women from 15 to 45 years of age) and motherhood in this country has reached a comparatively high level of safety, the rate is susceptible of reduction, for many of the deaths are preventable. A hundred years ago the rate is believed to have been 10 per thousand live births, so that there has been a considerable reduction. But for a number of years the rate has remained obstinately at 4, despite the great expansion in the maternity services and the remarkable improvement in the general health of the community.

The report states that in a number of cases the chances of recovery would have been greater had a practitioner experienced in midwifery been in attendance, had he had the assistance of an obstetric expert, or had the patient been admitted to the hospital earlier. It is therefore suggested that those general practitioners who undertake obstetric work under a local authority should be interested, experienced and actively engaged in the practice of midwifery and have sufficient time for unhurried work. It is recommended that in any maternity scheme the local authorities should provide one or more obstetric consultants. In certain types of case, arrangements should be made for bringing to the patient the services of a skilled hospital staff instead of subjecting her to the risks of transference to a hospital. Emergency units should be organized at maternity hospitals or at the maternity departments of general hospitals. Antepartum clinics conducted by an obstetric specialist, to which difficult cases can be referred, should be provided. The authorities should also make arrangements to secure an adequate supply of milk or other suitable food during pregnancy.

The Conservative Treatment of Acute Infections

In the *Edinburgh Medical Journal* Sir David Wilkie, professor of surgery in the University of Edinburgh, makes a strong plea for the conservative treatment of wound infections. He points out that Lister's great advance led to an endeavor to shorten and relieve the period of illness of acute infective lesions by means of the knife. The end of the last century and the early years of this century saw the zenith of active surgical attack in acute inflammation, whether in soft parts, serous cavities or bones. Pus must be evacuated at the earliest opportunity; if not present, tension must be relieved by free incision; open dependent drainage must be secured. But today the outlook is more biologic and it is recognized that the local and general changes of the reaction to local infection are an attempt to localize the infection and to mobilize the defenses of the body. Nothing should be done to interfere with this.

INFECTED PUNCTURED WOUND OF THE HAND WITH LYMPHANGITIS

The type of infected punctured wound of the hand in which there is lymphangitis is common in physicians and nurses and may be dangerous when derived from an infected lesion in a patient. Professor Wilkie considers it a grave mistake to incise the hand or finger in the first forty-eight hours. One must not break the barriers which nature is trying to set up. The value of treatment by passive congestion, according to the Bier method, is not sufficiently recognized. Repeated hot fomentations should be applied and 30 cc. of concentrated antitoxic serum given subcutaneously after desensitization.

BOILS AND CARBUNCLES

Incision of a boil on the supposition that it is a form of abscess Professor Wilkie considers wrong in theory and mischievous in practice. Complete immobilization by strapping is the most effective treatment. For carbuncle he recommends the same treatment. Probably bacteriophage develops under the occlusive dressing and inhibits the growth of *Staphylococcus aureus*. In severe toxic cases with danger to life he gives large doses of staphylococcus antitoxic serum.

ACUTE OSTEOMYELITIS

In acute osteomyelitis, physicians have been slow to abandon the dogmatic teaching of radical opening of the bone. But more and more it is being recognized that the bone lesion is a fixation abscess in a staphylococcal septicemia. Professor Wilkie has been immensely impressed by the Winnett Orr treatment—moderate free opening of the bone, packing the wound with sterile gauze treated with petrolatum and enclosing the whole limb in a plaster cast for from three to six weeks. The results are a striking illustration of the value of rest in acute inflammation and of the healing properties of wound secretions, commonly regarded as dirty and offensive. He considers that here again is a bacteriophage effect. In cases of profound toxemia, antistaphylococcus serum, with conservative local treatment, is the only hope.

ACUTE PERITONITIS

As a house surgeon Professor Wilkie participated in the heyday of the surgical attack on acute peritonitis, but experiments that he performed on rabbits by injecting a coccus of standard virulence into the peritoneum of rabbits immunized in greater or less degree showed that thick purulent exudate may be made up mainly of healthy leukocytes and is a favorable sign, while clearer exudate may be swarming with organisms and be of fatal import. The great lesson was that there is no surgical treatment for general peritonitis, though it may be prevented by timely surgery. It may be survived by natural resistance and certain complications may require surgical aid, but passive immunity by serum, fluid replacement if rendered necessary by vomiting, heat and morphine, as in the old days, are the things in which confidence must be placed. If streptococcus is present in the pus, antitoxic serum is indicated.

ACUTE PLEURAL EMPYEMA

When the late Professor Greenfield asked surgeons to operate on empyemas which he had been treating by aspiration for weeks, caustic comments were made. It took the appalling death rate of early open drainage of streptococcal empyemas in the American army in the great war to bring home to the profession Greenfield's teaching. Today physicians no longer condemn aspiration but use it until the pneumonic inflammation is on the wane and adhesions of lung to parietal pleura have formed. Then the residual pleural abscesses may be drained with safety. The swing back of surgery to a conservative outlook in these and other infective lesions shows the broader biologic outlook that is replacing the cruder and more dogmatically mechanical one of the skilful and anatomically trained craftsman.

The Crisis as it Affects the Profession

As referred to in previous letters, the *Concours médical*, a journal which devotes special attention to public relations problems confronting the profession, has received a number of replies from practitioners to the question of whether or not state medicine is desirable. Some are in favor of becoming government officials because it would assure them security in old age, which would be far better than to continue to see their means of livelihood taken away by the existing social insurance law and similar attempts on the part of the present socialist government to invade private practice. Other correspondents are strongly opposed to the idea of the profession giving up the existing personal relation of physician and patient, which is indispensable to success in treatment. A recent article by Dr. Mauguier of one of the smaller departments of France is quoted in the March 21 *Concours médical*. He states that there are three possible ways in which preventive medicine can be organized if the state insists on a greater degree of socialization of medicine than it claims to exist at present. These three are: 1. Organization by the state or by bureaus directly dependent on it, which would lead to making all physicians either state officials or at least paid by departments, communes, hospital commissions, social insurance bureaus, mutual health and accident private companies, or endowed foundations. 2. By the organized medical profession assuming complete charge of preventive medicine. This is the offer which is being considered by the government here at present. The profession, through its "*Syndicats médicaux*" which looks after the public relations of the profession, has unanimously voted to do this for the state, as referred to in previous letters. 3. By physicians as individuals.

In an editorial (*Concours médical* of March 21) Dr. Noir agrees with Dr. Mauguier that these three methods of organizing preventive medicine are the only feasible ones. Dr. Noir goes further and states that there is no sharp line of demarcation between preventive medicine and treatment of the sick. This is well illustrated in the present status of such a disease as syphilis. Is not the treatment, promptly instituted and periodically controlled by serologic tests, the only preventive method to check the spread of the disease? This has been carried out on a large scale in Paris and one rarely sees patients with complications of the primary or secondary stages. The same is true of pulmonary tuberculosis as well as for carriers of the acute infectious diseases. Antepartum care, medical inspection of schools, internment of cases of mental disease, and physical culture can all be grouped as preventive medicine efforts which have encroached on treatment of the sick to such an extent as to render this part of the physician's work almost superfluous. The greater the progress made in medical science, the less does there appear to be a difference between preventive and actual care of the sick. In view of this realistic state of affairs, what sort of attitude should the profession adopt? Sooner or later it will be forced to recognize the fact that for certain centers of population, for certain countries, only state medicine, or at least some form of government subsidy, will suffice. In other centers or countries, where unity exists among physicians, medical organization can be taken charge of by groups of physicians under the supervision of their syndicates or county societies. In addition, medicine as practiced by individuals as such should be able to continue to exist, especially in rural communities, provided the laboratory facilities in hospitals or rural health centers are placed at the disposal of such general practitioners. An ambulance organization ought to be so situated, near rural districts, as to be prepared to transport the sick to the hospital. These two things have been done in France for the indigent sick but not for the average wage earners.

Certain Eczemas and Urticarias

A paper on the acid-base equilibrium in certain eczemas and urticarias was read by Prof. Pasteur Vallery-Radot and his associates at the March 5 meeting of the Société médicale des hôpitaux. The variations of the acid-base equilibrium, hydrogen ion concentration of the urine and alkali reserve were noted in twenty-five cases of eczema and urticaria. They noted a frequent disturbance of the acid-base equilibrium in these two diseases, as well as in Quincke's edema. They found either a state of acidosis or of alkalosis and succeeded in reestablishing the acid-base equilibrium by diets and urine acidifiers or alkalinizing drugs, depending on the individual case. After a few days treatment, the hydrogen ion concentration of the urine and the alkali reserve became normal again, accompanied by an improvement in or disappearance of the cutaneous manifestations. An interesting case was reported of a patient who had urticaria only when there was acidosis and, on the other hand, only asthma when an alkalosis existed. This is a typical example of humoral instability and shows the influence of alkalosis and of acidosis on certain morbid conditions. The authors called attention to the necessity of always taking into consideration an acid-base dysequilibrium as a factor which certainly favors the appearance of cutaneous and probably of asthmatic manifestations.

Obligatory Mixed Vaccination of Medical Students

At the July 23, 1936, meeting of the Académie de médecine a committee was appointed to study the advisability of obligatory vaccination (antityphoid, antidiphtheria and antitetanic) of all medical students. The report of this committee was read by Professor Tanon at the meeting of the society March 9 of this year. The risk of tetanus infection being minimal, one could exclude this form of vaccination. However, the use of the mixed vaccine (antityphoid and antidiphtheria), the latter by the Ramon anatoxin, should be made obligatory for all medical students as soon as possible after beginning their first year. The report of the committee, subject to the approval of the ministers of public health and national education, was unanimously adopted.

Bacillus Ramosus Infection

Bacillus ramosus, described by Veillon and Zuber, belongs to a group of strictly anaerobic bacteria, which develops only at incubator temperature, does not form spores and is difficult to cultivate on artificial mediums. The bacilli are constantly present in the mouth, pharynx, intestine and female genital tract. The bacillus is gram positive and is termed *ramosus* because of the ramified form in which it is found in pathologic exudates and in cultures. It was found by Veillon and Zuber in the pus from cases of pulmonary gangrene, otitis, mastoiditis and appendicitis. In a few instances it has been found in blood cultures.

At the March 16 meeting of the Académie de médecine André Lemierre, Reilly and Bloch-Michel reported five cases of *Bacillus ramosus* infection observed at the Claude-Bernard hospital. The first case was one of gas gangrene due to *Bacillus ramosus* and aerobic hemolytic streptococci following a hypodermic injection. In contrast to infections due to *Bacillus perfringens*, which are uniformly fatal, the patient recovered after the use of large incisions. In the four other patients, *Bacillus ramosus* was isolated from the blood. In one of the latter patients the fact that the blood culture was positive only once out of five times raises the question as to whether the bacillus could have been only a transitory invader. In the three other (blood culture positive) cases the authors were also inclined to believe that the organism was a secondary invader. Compared to the gravity of infections due to *Bacillus funduliformis*, those due to *Bacillus ramosus* are comparatively benign. Hence one cannot consider infections due to the latter as being true septicemias.

The Misuse of Hypnotics

In recent years the misuse of hypnotic drugs has steadily come to the fore. From several countries an increase in the number of cases has been reported. The disquieting observation has also been made that, if a patient is suddenly deprived of the soporific, threatening phenomena of abstinence will appear just as in morphinism and these may in some cases lead to a fatal termination. Hoff and Kauders, as well as Seevers and Tatum, observed in animal experimentation that a prolonged administration of barbital (veronal) leads to a toxic state and that if a sudden deprivation then takes place it will be followed by severe phenomena of abstinence. Further experiments (reported in the *Klinische Wochenschrift*) have recently been carried on with dogs by H. Oettel and A. Krautwald at the Berlin Pharmacologic Institute. These investigators undertook to determine whether an addiction accompanied by phenomena of abstinence is favored by a more or less ready decomposition of the hypnotic. Four dogs received daily doses of various barbituric acid derivatives over a period of from four to seven months. The substances administered were (1) diethylbarbituric acid (barbital, veronal), (2) phenylethylbarbituric acid (phenobarbital, luminal), (3) cyclohexenyl ethyl barbituric acid (cyclobarbital, phanodorn) and (4) isopropyl-b-bromallyl barbituric acid (nostal). The dosages were selected in such a way that the dogs were just able to take spontaneous nourishment. In order to determine whether with habituation the decomposition within the organism would exhibit changes, the content in the urine was isolated, weighed and identified. The following observations were made: 1. Doses of barbital, which at the beginning would induce a deep sleep of some seven hours' duration, came gradually to induce shorter periods of sleep; at the end of seven months, for example, the same dose induced a sleep of from two to three hours. Sudden deprivation at the end of seven months was not followed by any phenomena of abstinence whatever. On the average, about 65 per cent of the substance was expelled unchanged. The habituated organism was thus able to eliminate the drug more rapidly than the unhabituated organism, although to be sure the decomposition was unaltered. 2. Habituation to phenobarbital was relatively quicker, initial severe metabolic disturbances vanished after a few weeks, and after several months the same dose produced but slight stupefaction and uncertainty of movement in the dogs. Phenomena of abstinence, in the sense of excitation, did not appear when the dosage stopped; on the contrary, a mild depression was observed. Despite visible habituation, some 25 per cent was excreted in unaltered form. 3. In the case of cyclobarbital too the dosage necessary to induce a constant sleep of from six to seven hours' duration had gradually to be increased from 75 mg. per kilogram to 130 mg. No phenomena of abstinence appeared when the drug was suddenly stopped. The amount decomposed remained constantly 20 per cent of the quantity administered in spite of increased dosage. Elimination appeared to take place more quickly. 4. Habituation to nostal was surprisingly rapid. At the beginning a dose of 50 mg. per kilogram induced deep sleep of from six to seven hours, but after a few days even doses of from 75 to 90 mg. per kilogram failed to induce sleep and at the end of a month scarcely any hypnotic effect was produced. Then only after receiving a dose of 195 mg. per kilogram did the dog sleep again for a few hours. The animal became habituated to even this high dosage. No phenomena of abstinence were observed. In the urine the bromide of nostal was found again, almost completely split up, as inorganic bromide. At the start of the experiment some 25 per cent was

excreted but four months later at the finish only 11.4 per cent was excreted. Thus, in contrast to the other barbituric derivatives, nostal was easily decomposed. (Individual reflex and metabolic manifestations and so on are not here particularized, since they are characteristic only of experiments with animals.)

These investigations showed in the case of all the substances studied that decomposition within the organism, when considered in proportion to the apparent habituation, was observed to remain almost constant. One is led to conclude, therefore, that the nervous system itself must tend to become less sensitive to the drug. Thus regular administration of barbituric acid derivatives over a long period may indeed lead to a chronic intoxication, but somatic or psychic phenomena of excitation can appear (during the period of administration or immediately after deprivation) only if the dosage is excessively high. Accordingly, it may be concluded on the basis of these experiments that a somatic addiction and "genuine" phenomena of abstinence, such as characterizes morphinism, for example, cannot be produced by hypnotic drugs of the barbituric group.

The Effects of War Gas

Dr. Muntsch, an authority on war gases, recently reported before the Tuberculosis Society of Southeastern Germany on his recent studies of the principal action of the gases on the respiratory and vascular systems. The generally accepted theory that the principal effect of phosgene (green cross) is a hydrochloric acid corrosion of the pulmonary alveoli fails to offer a satisfactory explanation for the appearance of pulmonary edema. It is a striking fact that the alveoli alone are attacked, whereas the upper respiratory passages remain uninvolved and furthermore pure hydrochloric acid vapor otherwise produced pulmonary edema only in concentrations 800 times stronger than phosgene. According to other theories, the absorption of phosgene into the blood stream results in alterations and softening of the brain, and the cerebral disturbance extending by way of the nervous system finally gives rise in turn to the pulmonary edema.

In experiments with rabbits, the electrocardiogram recorded a marked bradycardia and diminished respiration within three to four minutes following the inhalation of phosgene. Thus it is a question of a vagus stimulation that subsides as soon as the subject is no longer exposed to the gas. It seems singular that pulmonary edema should first appear several hours after the inhalation of phosgene. Prof. Rudolf Nissen, who for many years served as head physician of the Sauerbruch Clinic, Berlin, and who now resides in Istanbul, has established the fact that a strong stimulation of the vagus conduces to increased permeability of the pulmonary alveoli.

Accordingly, the indicated treatment (prophylactic or curative) of the pulmonary edema is narcosis with chloroform, tribrom-ethanol or a similar general anesthetic. In this way the stimulation of the vagus will be inhibited.

Death of Hermann Kümmell

Prof. Hermann Kümmell died at the end of February, just short of his eighty-fifth birthday. For German surgeons his passing means the loss of an illustrious colleague. When Hamburg University was founded not long after the war, Kümmell, who had served for many years as director of a large municipal hospital, was appointed ordinarius in the new school. Kümmell's decades of responsible service were marked by signal contributions to surgery. He was active in all branches of the field. He was the first German surgeon to perform an appendectomy, and this at a time when the operation was still considered a risky affair. As early as 1890, when appendicitis was still known as perityphlitis, Kümmell advocated radical interventions; by 1905 he had performed 1,000 appendectomies. He also called special attention to intestinal

obstructions, tumors of the bladder and peritoneal tuberculosis. Kümmell contributed notably to improved surgery of the brain and spinal cord, to the surgical treatment of prostatic hypertrophy, and particularly to the surgery of the gallbladder. As early as 1886 he performed the first choledochotomy. He was among the first to establish a roentgen center as a separate unit of a surgical section. The syndrome called after him "Kümmell's disease" or "Kümmell's kyphosis" has also come to be recognized. In collaboration with Bier and Braun, Professor Kümmell edited a body of work on surgical procedures that has become classic. His numerous descriptive monographs on urologic problems were particularly valuable contributions. Kümmell, the man, had about him something chivalrous and distinguished that commanded the admiration and respect of all who knew him.

MOSCOW

(From Our Regular Correspondent)

April 3, 1937.

Congress on Skin and Venereal Diseases

The fourth All-Union Congress on Skin and Venereal Diseases was held in Moscow, January 27-February 2. The following questions were discussed: (1) the tasks of combating venereal and skin diseases during the next five years, (2) developments in the treatment of syphilis and (3) skin reactions. Simultaneously a urologic conference was held, dealing principally with the treatment in renal diseases and gonorrhea. About 1,000 physicians and many guests participated. Among them were Henri Sellier, health minister of France, Professor Cavaillon, the general secretary of the International League for Struggle against Venereal Diseases, and Dr. Hecht of Czechoslovakia.

Since the last congress, which took place about seven years ago, venereal diseases in our country have sharply decreased. In 1925 Dr. Aubrecht examined all the inhabitants of 1,308 farms in the Vedeneye district of the Voronezh province, where he detected 1,649 cases of syphilis in 420 households. His investigations of the same households in 1935 gave only fifty-two patients in thirty households. A similar survey by Dr. Smelovsky in the Kuibyshev province in 1926 and 1936 revealed a syphilis reduction of 90 per cent. In the national republics, where the incidence of syphilis was even greater than in the rural population of Russia, there was an unusual decline in venereal diseases. In Kirghizia, between 1926 and 1935, the reduction is 67 per cent; in Udmurtia, 82 per cent; in Yakutia, 89 per cent (between 1929 and 1936). In the Buryat-Mongolia district, syphilitic infection among children under 10 years of age was 10.6 per cent in 1926, and 1.5 per cent in 1935.

In total, as was summarized in the recent report of Professor Raits, director of the Congenital Syphilis Clinic of the Maternity Protection Institute of the People's Commissariat of Health, congenital syphilis among children declined from 0.3 per cent in 1927 to 0.01 per cent in 1936. Professor Davidovsky of Moscow, a specialist in morbid anatomy, declared that in 110,000 necropsies performed in Moscow over a ten year period syphilis as a cause of morbidity dropped from 3.8 in 1928 to 1.6 in 1932, a reduction of 58 per cent.

The congress discussed measures for achieving the complete disappearance of syphilis in villages and national districts, where lack of elementary sanitary and medical measures formerly made the infection general, and it also discussed measures for the complete eradication of congenital syphilis. In all medical colleges, departments of male and female gonorrhea will be established. During 1937-1938 all gynecologists are to attend special courses to keep posted on recent developments in the treatment of venereal diseases.

In the House of Trade Unions a special session of the congress was held celebrating the fifteenth anniversary of the establishment of the State Institute of Skin and Venereal diseases, directed by Prof. V. M. Bronner. The next All-Union Conference will be held in 1941 in the city of Baku.

New Health Commissar

By decision of the presidium of the All-Russian Central Executive Committee, issued March 15, Peter Grigorievich Sergiyev has been appointed people's commissar of health of the Russian Socialist Federative Soviet Republic, replacing Gregory N. Kaminsky. The new commissar was born in 1893 and graduated from the Kazan Faculty of Medicine in 1918. He took part in the imperialist war and in the civil war. In 1927 he began his scientific work in the Moscow Tropical Institute and in 1934 became director of this institute. In 1935 he was appointed a member of the malaria commission of the Hygienic Committee of the League of Nations. For his scientific work in combating malaria and in parasitology, Sergiyev was awarded the degree of a doctor of medical science.

For assistant peoples' commissar of health of the Soviet Union, the presidium of the Central Executive Committee of the Union of Socialist Soviet Republics appointed S. T. Kantorovich, former People's Commissar of Health of the Ukrainian Soviet Socialist Republic, and Yekaterina G. Karmanova.

Medical Airplane Service

Dr. D. E. Palms, director of the Administration of First Aid Aviation, working under the auspices of the Executive Committee of the Red Cross and the Red Crescent Society, recently announced the operation of aviation first aid units in forty towns of the Soviet Union, including the Far North, the Pacific Coast, the Ural Mountains region, the Pamirs Mountain region and the Kazakhstan steppes. At the disposal of this first aid aviation service are a large number of planes of several types, including the S-2 amphibian. Each airplane is equipped with special stretchers, full sets of linen, warm clothing, medical instruments and medicines. The first aid aviation shows a marked growth, as can be seen from the accompanying table.

Growth of First Aid Aviation

	Number of Trips	Total of Hours	Kilometers Covered	Number of Patients
1935.....	1,499	3,972	476,640	365
1936.....	3,575	11,131	1,335,720	570

In 1936 the Moscow Province Aviation and Gliding School prepared for first aid aviation service a group of physicians and nurses, training half of them in parachute jumping, because physicians frequently have to descend in parachutes to render medical aid.

Marriages

FRANK H. HENDRICKS, Cleveland, to Miss Anna Belle Spaulding of Whitesboro, N. J., February 21.

GEORGE ALEXANDER LORD to Miss Katherine Ethel Lemon, both of Rochester, Minn., February 17.

JOSEPH WILLIAM MENDOZA, Pittsburgh, to Miss Marian Atran of McKeesport, Pa., April 28.

HARRY I. SNYDER, Pittsburgh, to Miss Sarah Venger of Beaver Falls, Pa., Nov. 8, 1936.

HAROLD L. DAVIS, Trenton, N. J., to Miss Carol Lowenstein of New York, May 14.

JOSEPH PALKOVITZ to Miss Gertrude Palkovitz, both of Pittsburgh, February 23.

Deaths

Joseph Isolin Mitchell ☉ Memphis, Tenn.; University of Tennessee College of Medicine, Memphis, 1919; member of the American Orthopedic Association, the Clinical Orthopedic Society, the Southeastern Surgical Congress and the American Academy of Orthopedic Surgeons; fellow of the American College of Surgeons; assistant professor of orthopedic surgery at his alma mater; orthopedic surgeon to the Willis C. Campbell Clinic, Crippled Children's Hospital School and Hospital for Crippled Adults; attending orthopedic surgeon to the Baptist Memorial, St. Joseph's and Memphis General hospitals; aged 41; died, April 7, of acute intestinal obstruction.

Jacob George Brody, Youngstown, Ohio; Western Reserve University Medical Department, Cleveland, 1908; member of the Ohio State Medical Association; instructor of pharmacology at Cornell University, New York, 1910-1922, teaching fellow at his alma mater, 1922-1925; assistant professor of physiology and pharmacology at the University of Georgia, 1925-1926, and later professor of physiology and pharmacology at the New York Homeopathic Medical College, New York; aged 59; member of the staff of St. Elizabeth's Hospital, where he died, March 21, of heart disease.

Dennis Rider Wood Crile ☉ Altadena, Calif.; Harvard University Medical School, Boston, 1917; member of the Illinois State Medical Society; fellow of the American College of Surgeons; at one time associate in surgery and anatomy at the University of Illinois College of Medicine, Chicago; formerly attending surgeon to the Augustana Hospital, Chicago, and surgical consultant to the United States Marine Hospital, Chicago; aged 45; was found dead, March 21, of an incised wound of the throat.

Louis Victor Waldron, Yonkers, N. Y.; New York University Medical College, New York, 1897; member of the Medical Society of the State of New York; past president of the Medical Society of the County of Westchester and the Yonkers Academy of Medicine; for many years director of child hygiene; health officer of Yonkers; aged 69; member of the staff of St. John's Riverside Hospital, where he died, March 13, of pneumonia following an automobile accident.

Isaac Newton Trent, Muncie, Ind.; Kentucky School of Medicine, Louisville, 1881; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1887; member of the Indiana State Medical Association; for many years a member of the state legislature; formerly senator; member of the staff of the Ball Memorial Hospital; aged 82; died, March 4, of arteriosclerosis and bronchopneumonia.

Robert W. Berrey, Mexico, Mo.; Missouri Medical College, St. Louis, 1883; member of the Missouri State Medical Association; deputy state health commissioner in Audrain County; formerly mayor of Mexico; at various times county coroner, city councilman and member of the board of education; aged 75; died, March 15, of arteriosclerosis.

Edwin Charles Beer, Toronto, Ont., Canada; Trinity Medical College, Toronto, 1903; served with the Canadian Army during the World War; member of the board of education, 1920-1925, and for two years medical examiner; at various times, on the staffs of St. Michael's Hospital and Toronto East General Hospital; aged 60; died, March 3.

Thomas Edward Caulfield ☉ Woburn, Mass.; Harvard University Medical School, Boston, 1902; member of the New England Obstetrical and Gynecological Society; served during the World War; formerly city physician; chief surgeon at the Choate Memorial Hospital; aged 57; died, March 8, of periarteritis nodosa.

Horace R. McCarroll, Walnut Ridge, Ark.; Memphis (Tenn.) Hospital Medical College, 1903; member of the Arkansas Medical Society; past president and secretary of the Lawrence County Medical Society; aged 65; died, March 4, in San Antonio, Texas, of myocarditis, hypertension and arteriosclerosis.

George Edward Maurer ☉ New York; New York University Medical College, 1896; veteran of the Spanish-American and World wars; formerly chairman of the district school board and medical inspector in the department of health; aged 70; died, March 17, in the Wickersham Hospital, of pneumonia.

John Warden McCauley ☉ Rochester, N. Y.; University of Pennsylvania Department of Medicine, Philadelphia, 1887; one of the organizers, members of the board of directors and member of the staff of the Park Avenue Hospital; aged 76; died, March 10, of mesenteric thrombosis and arteriosclerosis.

Ulysses Grant Anderson, Carbondale, Pa.; Columbian University Medical Department, Washington, D. C., 1902; member of the Medical Society of the State of Pennsylvania; on the staff of the Carbondale General Hospital; aged 71; died, March 28, in St. Joseph's Hospital, of cerebral hemorrhage.

Julian Cowley Smith ☉ Oneonta, N. Y.; University of the City of New York Medical Department, 1892; served during the World War; formerly member of the state legislature; on the consulting staff of the Otsego County Sanitarium, Mount Vision; aged 71; died, March 5, in Lakeland, Fla.

Robert B. McKeeman, Fort Wayne, Ind.; Fort Wayne College of Medicine, 1897; member of the Indiana State Medical Association; vice president of the Fort Wayne Medical Society; on the staff of the Lutheran Hospital; aged 63; died, March 4, of pneumonia.

James Cleon Creel ☉ Parsons, Kan.; Marion-Sims College of Medicine, St. Louis, 1899; on the staff of the Mercy Hospital; medical superintendent of the Missouri-Kansas-Texas Railroad Employees' Hospital; aged 69; died, March 21, of cerebral hemorrhage.

Joseph Wilfred Bonnier, Montreal, Que., Canada; School of Medicine and Surgery of Montreal, Faculty of Medicine of the University of Laval at Montreal, 1899; formerly statistician of the health department of the province of Quebec; aged 64; died, February 12.

John F. Roderer, Philadelphia; University of Pennsylvania Department of Medicine, Philadelphia, 1884; member of the Medical Society of the State of Pennsylvania; on the staff of the Joseph Price Memorial Hospital; aged 80; died, March 7, of myocarditis.

Sylvester Irvin Arthur, Patoka, Ind.; St. Louis University School of Medicine, 1907; member of the Indiana State Medical Association; past president of the Gibson County Medical Society; aged 73; died, March 15, of angina pectoris and nephritis.

Leo I. Mishkin ☉ New York; University and Bellevue Hospital Medical College, New York, 1910; aged 51; on the staffs of the Jewish Maternity Hospital, Beth Israel Hospital and the Mount Sinai Hospital, where he died, March 4, of heart disease.

Melbourne Mabey ☉ Santa Ana, Calif.; Northwestern University Medical School, Chicago, 1911; fellow of the American College of Surgeons; served during the World War; on the staff of the Santa Ana Clinic; aged 60; died, March 23, of heart disease.

Benjamin Earl Niebel, Brigantine Beach, N. J.; Jefferson Medical College of Philadelphia, 1912; member of the Medical Society of the State of Pennsylvania; formerly a medical missionary in China; aged 50; died, March 5, of carcinoma of the colon.

Robert Lemmon ☉ Lexington, Va.; University of Virginia Department of Medicine, Charlottesville, 1902; was a lieutenant in the medical reserve corps of the army from 1908-1913; post surgeon to the Virginia Military Institute; aged 58; died, March 6.

Noble Smith Howard, Harlan, Ky.; Louisville Medical College, 1894; member of the Kentucky State Medical Association; past president of the Harlan County Medical Society; member of the city council; aged 77; died, March 5, of coronary occlusion.

Martin John Schwanz ☉ Plymouth, Mich.; Saginaw (Mich.) Valley Medical College, 1900; Detroit College of Medicine, 1904; served during the World War; aged 65; died, March 9, in the Harper Hospital, Detroit, of sarcoma of the tonsil.

William Henry Wundram, Detroit; Indiana University School of Medicine, Indianapolis, 1922; aged 41; member of the staffs of the Receiving Hospital and the Harper Hospital, where he died, March 11, of uremia and cerebral hemorrhage.

Charles Francis Yerdon, Brooklyn; Baltimore Medical College, 1897; member of the Medical Society of the State of New York; served during the World War; member of the staff of the Kings County Hospital; aged 70; died, March 5.

John William Osborne, Champaign, Ill.; Rush Medical College, Chicago, 1902; member of the Illinois State Medical Society; aged 58; for many years on the staff of the Burnham City Hospital, where he died, March 11, of diabetes mellitus.

James Chasey, West Long Branch, N. J.; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1875; member of the board of education; aged 83; died, March 29, of chronic myocarditis and arteriosclerosis.

William Ward Syp ☉ Centerville, Iowa; State University of Iowa College of Medicine, Iowa City, 1895; formerly on the staff of St. Joseph's Mercy Hospital; aged 64; died, March 3, in Santa Ana, Calif., of coronary thrombosis.

Walter M. Chavis, Pine Bluff, Ark.; Gate City Medical College, Dallas, Texas, 1903; member of the Arkansas Medical Society; formerly sheriff and coroner in Ashley County; aged 59; died, March 14, of cerebral hemorrhage.

Stafford G. Cooke, Yorktown, Va.; College of Physicians and Surgeons, Baltimore, 1886; for many years supervisor in Nelson district of York County, and member of the school board; aged 76; died suddenly, March 2.

Edward Beardslee Skellenger, Trenton, N. J.; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1875; aged 85; died suddenly, March 8, of chronic myocarditis and arteriosclerosis.

Samuel W. Lehman, Dixon, Ill.; Rush Medical College, Chicago, 1899; member of the Illinois State Medical Society; formerly on the staff of the Dixon Public Hospital; aged 70; died, March 9, of chronic myocarditis.

Ethelbert O. Cosman, Minneapolis; Cincinnati College of Medicine and Surgery, 1885; member of the Minnesota State Medical Association; aged 76; died, March 21, of diabetes mellitus and hypertensive heart disease.

John Joseph Carroll, Covington, Ky.; College of Physicians and Surgeons, Boston, 1920; member of the Kentucky State Medical Association; served during the World War; aged 48; died, March 21, of pneumonia.

Ledru White Bayne, Hattiesburg, Miss.; University of Nashville (Tenn.) Medical Department, 1899; member of the Mississippi State Medical Association; aged 65; died suddenly, March 20, of heart disease.

Dio David Brenaman, Detroit; Wayne University College of Medicine, Detroit, 1936; resident to the Herman Kiefer Hospital; aged 29; died, March 5, in the Harper Hospital, of abscess of the liver.

Mary Alice Burke ☉ Springfield, Mass.; Woman's Medical College of Pennsylvania, Philadelphia, 1917; member of the staff of the Mercy Hospital; aged 53; died suddenly, March 25, of heart disease.

James Alfred Young, Bunkie, La.; Hospital College of Medicine, Louisville, Ky., 1906; aged 65; died, March 6, in a sanatorium at Lecompte, of uremia, nephritis and carcinoma of the prostate.

Charles Walker Mathers, Carlisle, Ky.; Miami Medical College, Cincinnati, 1879; at one time state senator and bank president; formerly county judge; aged 81; died, March 7, of peritonitis.

William Vernon Davis, Booneville, Miss.; Kentucky School of Medicine, Louisville, 1895; member of the Mississippi State Medical Association; aged 74; died, March 7, of coronary occlusion.

Harry Eugene Wiley ☉ Philadelphia; Jefferson Medical College of Philadelphia, 1891; aged 66; died, March 14, in the Lankenau Hospital, of nephrosis and arteriosclerotic heart disease.

Marie Louise Bauer ☉ Philadelphia; Woman's Medical College of Pennsylvania, Philadelphia, 1890; aged 74; died suddenly, March 18, of rupture of the aorta and arteriosclerosis.

Henry A. Cox, Rayville, Mo.; University Medical College of Kansas City, Mo., 1900; aged 58; died, March 26, in a sanatorium at Kansas City, of hypostatic pneumonia and myocarditis.

Sarah V. Tilton, Rossville, Ill.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1882; aged 83; died, February 14, in a hospital at Danville, of arteriosclerotic heart disease.

Philip Emanuel Marsh, Otter Lake, Mich.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1900; aged 80; died, March 6, of acute dilatation of the heart.

Luther G. Bass, Chicago; Rush Medical College, Chicago, 1880; member of the Illinois State Medical Society; aged 88; died, March 20, of coronary thrombosis and arteriosclerosis.

John Grover Scifres, Indianapolis; Indiana University School of Medicine, Indianapolis, 1908; aged 53; died, March 1, in the Methodist Hospital, of cerebral edema.

Abraham Finkelppearl, Pittsburgh; University of Pittsburgh School of Medicine, 1913; served during the World War; aged 45; died, March 7, of acute pulmonary edema.

Charles B. Lanneau, Flat Rock, N. C.; Medical College of South Carolina, Charleston, 1869; Confederate veteran; aged 90; died, March 6, of chronic myocarditis.

Samuel Henry Hartwell, Bellepoint, W. Va. (licensed in West Virginia by the state board of health, year unknown); aged 81; died, February 7, of myocarditis.

Coleman Ferrell Pearson, Montgomery, Ala.; Medical College of Alabama, Mobile, 1900; aged 60; was found dead, March 4, of a self-inflicted bullet wound.

John Edward Doerr ☉ Mount Vernon, Ind.; University of Pennsylvania Department of Medicine, Philadelphia, 1891; aged 71; died, March 7, of myocarditis.

Cornelius L. Cork, Ralph, Ala.; Memphis (Tenn.) Hospital Medical College, 1904; aged 57; died, March 4, in the Druid City Hospital, Tuscaloosa, of pneumonia.

Alfred Tremblay ☉ Moline, Ill.; Detroit College of Medicine, 1906; on the staff of the Moline Public Hospital; aged 60; died, March 1, of coronary thrombosis.

Harriet Pervier Hooper, Syracuse, N. Y.; College of Physicians and Surgeons, Boston, 1893; died, March 30, of bronchopneumonia and arteriosclerosis.

Joseph Sanders Strother, Blue Springs, Mo.; Louisville (Ky.) Medical College, 1877; aged 79; died, March 1, of coronary thrombosis and arteriosclerosis.

Percy G. Smith, New York; Columbian University Medical Department, Washington, D. C., 1895; died, March 7, in St. Vincent's Hospital, of pneumonia.

William George McCullough, Trenton, N. J.; Hahnemann Medical College of Philadelphia, 1878; aged 85; died, March 8, of carcinoma of the axilla.

C. Marion Glock, Arcola, Ind.; Fort Wayne College of Medicine, 1903; bank president; aged 60; died, March 8, of heart block and pulmonary edema.

Wesley Sherman Miller, Palatka, Fla.; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1908; aged 54; died, March 5, of angina pectoris.

Joseph John Cody, Boston; College of Physicians and Surgeons, Boston, 1903; aged 56; died suddenly, March 14, of coronary occlusion and sclerosis.

John Burton Armstrong, Beaver, Pa.; Western Pennsylvania Medical College, Pittsburgh, 1891; aged 69; died, March 22, of cerebral arteriosclerosis.

Thurlow W. Brimigton, Coplin Plantation, Maine; (licensed in Maine, under the Act of 1895); aged 67; died, March 14, of a self-inflicted bullet wound.

Elizabeth Taylor Wright ☉ Atlantic City, N. J.; Boston University School of Medicine, 1908; aged 65; died, March 17, of cerebral hemorrhage.

Alfred W. Trevitt, Wausau, Wis.; Eclectic Medical Institute, Cincinnati, 1881; for many years postmaster; aged 76; died, March 10, of senility.

George Washington Lancaster, Pisgah, Tenn.; Vanderbilt University School of Medicine, Nashville, 1892; aged 71; died, March 7, of heart disease.

Marion A. Born, Athens, Ga.; Southern Medical College, Atlanta, 1891; aged 64; died, March 23, of aneurysm of the aorta and pellagra.

Frank M. Murtaugh, Jackson, Tenn. (licensed in Tennessee in 1910); formerly city health officer; aged 56; died, March 3, of pneumonia.

William R. Hubbert, Detroit; Detroit Medical College, 1885; aged 78; died, March 1, in Miami, Fla., of carcinoma of the liver.

Daniel Christy, Shippingport, Pa.; Cleveland Medical College, 1897; aged 64; died suddenly, March 2, of chronic myocarditis.

John Edward Love, Whiting, Kan.; Rush Medical College, Chicago, 1882; aged 78; died, March 3, of cerebral hemorrhage.

William E. Paxton, Denver; Ensworth Medical College, St. Joseph, 1900; aged 77; died, March 11, of lobar pneumonia.

Vincent C. Brunson, Newville, Ind.; Toledo (Ohio) Medical College, 1884; aged 81; died, March 15, of pneumonia.

Franklin P. Sager, Ada, Ohio; Columbus Medical College, 1880; aged 83; died, March 23, of cerebral hemorrhage.

William Henry Forgy, Elkton, Ky.; Louisville Medical College, 1886; aged 86; died, March 9, of senility.

Allen Wilson, St. Louis; Missouri Medical College, St. Louis, 1879; aged 87; died, March 3, of asthma.

James Henry Brill, Indianapolis; Miami Medical College, Cincinnati, 1872; aged 93; died, February 3.

Thomas J. Wilkinson, Athens, Ala. (licensed in Alabama, year unknown); aged 66; died, February 10.

Correspondence

"RELATION OF AMERICAN MEDICAL ASSOCIATION TO CERTIFICATION OF SPECIALISTS"

To the Editor:—In THE JOURNAL, March 27, there appeared an article, "Relation of American Medical Association to Certification of Specialists," by Dr. Charles G. Heyd. Were this article merely the expression of opinion of a member or Fellow of the Association, no particular comment would be indicated; but such is not the case. The opinion of the President must in some measure represent the attitude of the Association and is, furthermore, an opinion which will influence the action of the House of Delegates and various committees of the Association and must carry some weight with the special boards. In the main the ideas and purposes expressed in this article are admirable, but on two critical points I would like to take exception to the expressions of the opinion of the author.

On page 1019, column 1, paragraph 4, is this statement: "We must be on our guard against any such thing as multiple certification or certification by one or more of the boards of certification." This is but an indication of a more extensive attitude of similar nature held by some of the special boards, which hold in addition that the candidate for certification must limit his practice to the given specialty. This attitude must go beyond all desirable objectives of these special boards. Certainly their purpose must be to certify that a given individual is a competent practitioner in a special field. It cannot and should not be their purpose to dictate to their candidates and diplomates how they should practice medicine or what particular cases they should see. The development of additional boards, say in gastro-enterology, would thus prevent a certified gastro-enterologist from taking care of a patient with coronary disease who came to him as a sufferer from indigestion. Far fetched, you say. Such special boards will never be developed. Not at all! They have been developed, they exist now in other fields. For instance, there is a special board for otolaryngology and another for ophthalmology. Certainly there can be nothing unreasonable in the certification of the practitioners properly qualified in both fields by both boards. In fact, such a course must be desirable. In many smaller cities it will be impossible for representatives of both specialties to exist. The boards, if the suggestion of Dr. Heyd is followed, must either deny to such men the certification to which they are entitled or deny to the smaller communities the special facilities which they need.

It would seem reasonable that the sole desirable function of the special boards is to exercise an advisory influence over special training and to certify to the special qualifications of individual practitioners. If a given individual is capable of acquiring the special information and training and of utilizing this training in fields of medical practice which fall in the domain of more than one board, he is entitled to the certification that he possesses such qualifications. For the boards to step beyond these limits into the dictation of what those they will and have certified should practice must be undesirable. Such a practice will freeze the medical profession in this country into compact isolated groups of specialists with the unfortunate results that obtain in other countries with the sharp differentiation between physicians and surgeons.

The second point on which I would differ sharply with Dr. Heyd is found on page 1019, column 1, paragraph 6. There he states: "It would seem wise that the question of research work should not be part of the examination of a candidate for certification." Dr. Heyd's meaning here is not quite clear, and perhaps I have misinterpreted his intent. I assume that he means that a certain amount of research work should not be one of the requirements for admission to certification and with

that I should be forced to agree; not because such work would be undesirable but because of the practical difficulty for all applicants for certification to obtain opportunity for such work at the present time. However, the boards should encourage all applicants to have such investigative experience and this by implication Dr. Heyd decries. Why? Because they will not all become a Koch, a Pasteur or a Banting. Of course not; but some of them will. However, that is not important; the majority of the capable men will find or create suitable opportunities. The point is that a measure of experience with investigative work is important for all who would aspire to specialization in a given field not because of their individual contributions, which may or may not prove valuable, but because of the training for the individual. Such experience with the proper type of investigative work will train the individual in scientific method, scientific accuracy, will bring him into contact with the scientific literature and with the work of others in his special field, will give him some basis for being critical of the results of work of others by teaching him the difficulties, the pitfalls and the necessity for adequate controls in acceptable investigative work. It has been long recognized that much clinical investigation is not on a par with comparable laboratory and animal experimentation. If proper adaptation of the results of laboratory work is to be made in the clinic, clinical investigation must be as carefully executed and controlled as the laboratory work. This will never be attained until the clinician is thoroughly grounded in scientific methods. Certainly the present period with the rapidly advancing frontiers of medicine is no time to denounce investigative training. Although such training is not at present attainable by all who would be specialists, such a requirement is a desirable end to strive for.

Certainly the special boards may prove highly desirable. But if they are to achieve their full usefulness they must not hamper the progress of the medical profession; they must not cast it into rigid molds and they must look forward from a vantage point far in front of the great mass of the profession.

PAUL C. BUCY, M.D.

Division on Neurology and Neurosurgery,
University of Chicago.

[NOTE.—This letter was referred to Dr. Heyd, who replies:]

To the Editor:—I agree with Dr. Bucy that the purpose of the special boards is to certify that a given individual is a competent practitioner in a special field. The assumption of specialistic training by any practitioner of medicine without first being willing to submit his credentials as to his special training is incompatible with his responsibility to society. If a physician seeks to be registered as a specialist he must prove his competence in a special field; but I do not think one can read into my article any curtailment of the rights of physicians to practice medicine or surgery.

I can see no reason why a gastro-enterologist, either certified or not certified, would be prevented from taking care of a patient with coronary disease, whether that patient came to him as a sufferer from indigestion or not. Here the question involved is an ethical one as to the competence of the gastro-enterologist to treat coronary thrombosis and not one of certification.

I realize that in certain communities it will be necessary for certain practitioners to practice "eye, ear, nose and throat" and I can see no particular reason why a practitioner could not be certified in ophthalmology and/or in otolaryngology if he could pass the examinations.

I think that Dr. Bucy has misinterpreted my intent with regard to research. There are certain national societies that make a contribution in research a prerequisite for admission to the society. It seemed to me unwise if a physician applied for certification in a given specialty to make him furnish satisfactory evidence of worth-while research work. It is probable that the certified men will try to do research and it is highly

desirable that they should, yet the certification as a specialist should not be predicated on his research qualifications but on his competency as a specialist.

Experience will demonstrate that certain modifications may be necessary and certainly we do not wish "to cast the medical profession into rigid molds."

CHARLES GORDON HEYD, M.D., New York.

[In further elucidation of his argument, Dr. Bucy writes as follows:]

To the Editor:—Dr. Heyd does not seem to feel that there is any real threat by the special boards toward limitation of the field of medical practice. In proof of the existence of this danger I should like to quote from the pamphlet issued by the American Board of Obstetrics and Gynecology, sixth issue, September 1936:

Page 6: "Each applicant, before he shall become eligible to receive such certificate or other evidence of recognition . . . (d) must assure the Board that he is limiting his practice to obstetrics and (or) gynecology and that he intends to continue to do so; . . ." (italics in original).

Page 7: "The Board has ruled that physicians who accept male patients in their private or other practice, for operative or other care, cannot be regarded as specialists in obstetrics and gynecology."

If the special boards can limit the physician's practice in one direction they can do so in another. And if the ultimate aims of the special boards are achieved, to wit, to have only diplomates of the various certifying boards accepted on the staffs of approved hospitals, and the faculties of approved medical colleges, and listed as specialists in the American Medical Directory, then this threat becomes a serious limitation on the medical profession of this country and the profession will be cast "into rigid molds." PAUL C. BUCY, M.D., Chicago.

THE ROENTGENOLOGIST AND THE HOSPITAL

To the Editor:—In the leading editorial in THE JOURNAL, April 10, you discuss the "thought provoking" report of the American Foundation and approve its realization "that diagnosis must precede prognosis and treatment." I heartily agree with this statement. However, in general, if a diagnosis is to be properly made you will grant that it should be made by a physician, yet the statements in your third paragraph virtually imply the opposite.

I wonder whether your readers realize the full import of these four sentences, which I quote from your editorial:

More and more hospitals are being equipped with competent clinical laboratory service, roentgenologic departments, physical therapy departments and serologic units. These methods are expensive and cannot be utilized to the fullest for all the patients who might benefit by their utilization without more permanent and more adequate financial support either to the hospitals directly or to the patients who require the services. Moreover, many states now provide, through their departments of health, laboratory services which may be utilized by the general practitioner for needy patients. Extension of such services should be of great benefit to the public health and should raise the general quality of medical care when a sufficient number of trained personnel becomes available.

In other words, clinical pathology and radiology "cannot be utilized to the fullest without more permanent and more adequate financial support to the hospitals or patients, and extension of such services should be of great benefit." It reads as though you believe these services were hospital and not medical services. One might as well argue that surgical operations and obstetric deliveries are expensive and that "they cannot be utilized to the fullest without more adequate financial support to the hospitals." Hospitals need more and better operating and delivery rooms, but the provision of such would not give surgery to patients at cheaper rates; such would increase hospital costs, not decrease medical costs.

Even a cursory glance at the ethics of the American Medical Association will convince one that the financial support of the hospitals should have nothing to do with the quality or extent of medical service performed in them, not by them. If radiology and pathology, the cornerstones of medical diagnosis, are to be practiced so as to give the greatest benefits to the public, they should be practiced as are the other branches of medicine. If we socialize those branches we shall inevitably socialize the other branches of medicine. The House of Delegates of the American Medical Association has declared that radiology and pathology should be practiced by doctors, not by hospitals.

If "compulsory insurance . . . subtly and continuously lowers the quality of medical care, the quality of the medical man," does not this also apply to radiologists and pathologists? Is it not already true that because of hospital domination of radiology and pathology it is almost impossible to get the best medical students to enter these fields? The best equipment is of little value if physicians of the highest intelligence are not available to operate it. It is important to the future of radiology and pathology that we learn to distinguish between good equipment and good medical service. Good diagnostic service requires more and better equipped doctors more than the provision of well equipped x-ray departments.

Adequate medical care cannot be standardized for distribution until many of the fundamental needs of our people are satisfied. Adequate medical diagnosis cannot be standardized by state supported, politically operated laboratories, any more than the practice of medicine can be standardized by state appointed and politically controlled general practitioners. The American Medical Association promotes the welfare of the public health by protecting those fundamentals of medical practice which have proved themselves through the years. One of those fundamentals is the personal responsibility of the physician to his patient. This responsibility would be destroyed by the methods you comment on; the radiologist and pathologist would be responsible to his political superior, not to the patient.

L. H. GARLAND, M.D., San Francisco.

"THE ADDIS COUNT IN CHILDREN FOLLOWING CLINICAL RECOVERY FROM POSTINFECTIONOUS NEPHRITIS"

To the Editor:—In the article entitled "The Addis Count in Children Following Clinical Recovery from Postinfectious Nephritis," by H. H. Boyle, C. A. Aldrich, Albert Frank and Sydney Borowsky, Chicago (THE JOURNAL, May 1, p. 1496), the statement is made that "a difference of one cell per square in the chamber makes a difference of 10,000 in the total specimen."

Feeling that this statement is somewhat misleading, I should like to clarify the method of calculation.

The calculation of the total urinary sediment of the twelve-hour specimen is the object of the test. In this series (Boyle and others) from 120 to 150 cc. of urine was about the average twelve-hour output. In determining the amount of urinary sediment present in this total, a 10 cc. sample of the total is taken, centrifugated according to the accepted technic, and the supernate withdrawn by pipet, usually 1 cc. of urine being left behind, so that the entire sediment of the 10 cc. sample is contained in the 1 cc. of urine. The cells in the sediment are counted in unit volumes of 0.1 cu. mm., so that one cell counted represents 10,000 cells in the 1 cc. of concentrated sediment, which represents 10 cc. of the total specimen. Under the conditions mentioned, with a total specimen of 150 cc., one cell counted on the hemocytometer would represent 150,000 cells in the total sediment for twelve hours. Casts are counted in unit volumes of 0.9 cu. mm.

ALBERT FRANK, M.D., Chicago.

Children's Memorial Hospital.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

TREATMENT OF CORONARY THROMBOSIS

To the Editor.—Two and one-half years ago a man, aged 35, with a negative previous history and apparently in perfectly good health, was suddenly seized with severe substernal pain, which radiated down his right arm. When examined, about an hour after the onset of the attack, he was apparently in severe pain, in semishock and with marked pallor, cold, clammy skin, large beads of perspiration on his forehead, and a slow regular pulse rate of 52. A diagnosis of acute coronary thrombosis was made and the patient was hospitalized. An electrocardiogram taken the day of his attack was normal except for some left ventricular preponderance. The subsequent clinical course fully confirmed the original diagnosis. There was a subsequent elevation of temperature to 100.4 F. for three days, an increased sedimentation rate and a fall in blood pressure from 130/90 to 105/80. There were also definite electrocardiographic changes; two days after the onset of his illness there was noted a definite inversion and curving of the T wave in lead 3 (this had previously been upright and no digitalis had been administered). One week later the electrocardiogram also showed T₂ to be slightly inverted. After eight weeks of hospitalization, the patient was allowed to resume gradually some activity. However, for about a year thereafter he complained of almost daily substernal pressure after slight activity; this would quickly be relieved by lying down, and after ten or fifteen minutes in the prone position he would again feel all right. During the past year, these attacks of substernal pressure have become less pronounced. However, he still complains of occasional attacks of definite substernal oppression, especially after excitement of any sort or on walking more than a few blocks. Walking up an incline, even if only of slight degree, seems especially to bring on this substernal pressure. Moreover, he complains of being very easily fatigued, after even the slightest undue activity, whereas before his present illness he seemed to have an unlimited source of energy and was a tireless worker. His physical examination at the present time is essentially negative. His heart sounds are normal and the heart is not enlarged. The blood pressure varies between 145/100 and 125/90. The Wassermann reaction is negative. His pulse is regular, the rate is 68, and within three minutes after moderate exercise it returns to normal, although there is a slight dyspnea. The vital capacity test shows about 10 per cent below the normal capacity. The electrocardiogram shows nothing unusual, except that T₃ has remained inverted. Lead 2 now appears normal. The question is just how much reliance should be placed on the symptoms at the present time, in the absence of definite physical signs of coronary disease? He is at present receiving a fair income from an insurance company as being totally disabled from doing any gainful occupation. He feels that he wants to get back to work and on the other hand is afraid that he will not be physically able to exert the energy outlay involved in such a course. Would I be justified in concluding that in view of his previous history and present complaints he is still unable to resume his occupation, which is a highly specialized work and entails considerable mental strain and also moderate physical activity? Would it be hazardous to consider the present symptoms as a neurotic basis and thus recommend his return to work? Granted that there is no subsequent acute attack of coronary thrombosis, how long would it be reasonable to suppose that such symptoms as now presented are on a real organic basis—the result of narrowing of the coronary vessels due either to sclerosis or to spasm? What, in general, is the prognosis of such a case of coronary involvement in a relatively young man, who has no signs of any other pathologic condition? Also what therapy would you recommend?

M.D., California.

ANSWER.—In a case of this type there are so many factors that must be carefully assessed that it is difficult to set out any but the most flexible rules for guidance. Three points must be carefully considered: first the amount of damage and the amount of recovery from the attack, second the probability of subsequent attacks, and third the extent of the neurotic element in this case.

After two and one-half years, further improvement will be slight and slow in appearing. It is even probable that there will be no further improvement. It is evident, however, that there has been enough cardiac efficiency in this patient to permit him considerable activity. The symptoms described cannot be disregarded even in the absence of physical signs, because only too often the symptoms are the sole evidence of coronary insufficiency. There is no definite time interval after which the symptoms cease to be on an organic basis.

With these points in mind it should be possible to hazard a guess as to the patient's physical ability to do the work he wishes to engage in. In general, it may be safe for him to do any work that does not cause an appreciable amount of distress. This brings us to a consideration of the second point.

It cannot be granted that a subsequent acute attack may not occur. The conditions that permitted the first attack to occur still exist and a subsequent attack is certainly a probability. As a rule there is no certainty that abstinence from work will

prevent a recurrent attack but there are certain types of work, notably those types which subject the patient to emotional strains and which are, mentally, of a highly competitive nature, that are very likely to bring on subsequent attacks. Because of this fact, physical ability to work is not the only guide to be followed.

With regard to the third point, it is most difficult to determine the extent of the neurotic element in any case of this sort. The physician certainly helps to make the patient "heart conscious" by the rigor of his immediate treatment of the attack. This is quite necessary, but some patients are unable to overcome this fear as the physical condition improves. At present the only guide that can be used to separate the "neurotic" from the "organic" patient (and this is a most unsatisfactory guide) is the deliberate and studied opinion of the attending physician. It is most disheartening to assure a patient that he may safely embark on a task and have him suddenly die from a "heart attack" on the following day.

In general, the prognosis following acute coronary thrombosis is not good. Age is not an important factor in the prognosis and the individual case must be considered. Those who make a good recovery and are able to adjust themselves, both mentally and physically, to the needs of their condition frequently do very well and live comfortably for years. These cases are the exception rather than the rule.

The therapy here should be that of the usual case of coronary occlusion. Intelligent management is the most valuable therapeutic agent. This should include avoidance of physical strain, overeating, and overstimulation of all kinds. The use of substances of the purine-base group, or the use of tissue extracts or the adenosines may be helpful. Surgery is as yet too uncertain to be recommended.

SURGERY OF HAND AFTER DIVISION OF ULNAR NERVE

To the Editor.—A patient of mine, a youth of 21, fell and cut his left hand on a broken milk bottle six months ago. The hand was cut in two sites, one on the proximal part of the hypothenar eminence, the other a very deep one (he extracted a large piece of glass from it) in the middle portion of the palm one inch distal to the wrist. He received treatment at a hospital, where the bleeding was stopped but the wounds were not inspected to see what structures were severed. Immediately following the injury there was anesthesia of the fourth and fifth fingers with flexion and inability to extend them fully. These symptoms have since improved about 50 per cent under massage, baking and exercise. Two months ago, however, the patient noticed an atrophy of the hand. This atrophy has become marked, being especially noticeable on the dorsum between the thumb and the index finger. The powers of adduction and abduction of the fingers and thumb (when the flexor and extensor tendons are not used) is completely gone. I thought that this was due to the severance of the deep (muscular) branch of the ulnar nerve, paralyzing the interossei muscles, adductor pollicis and so on. What should be the treatment at present? Is surgical intervention to attempt to reunite the severed nerves indicated now? What are the chances for success of such an operative procedure?

M.D., Pennsylvania.

ANSWER.—The symptoms described are those of division of the ulnar nerve in the palm. This is evidenced by the loss of sensation over the fourth and fifth fingers, atrophy of the interossei, and the motor disturbances symptomatic of paralysis of the interossei and the medial two lumbrical muscles. The presence of sensory loss over the ring and little fingers means, of course, that sensory division of the ulnar nerve has been divided, as well as the deep motor division.

What should be done at the present moment will depend somewhat on the healing of the original wound following its suture. If healing of the injury occurred by primary intention, without infection or discharge, operative repair of the divided nerves and all tendons (of which there are probably one or two divided) should be attempted now. If there was a serious postoperative infection with prolonged discharge and sepsis, it would be wise to wait for a period of from eight months to a year after the complete subsidence of discharge before attempting repair.

In performing the repair the operation should be done under a general anesthetic and in a bloodless field, secured by means of a blood pressure apparatus pumped up to 240 mm. of mercury. Great care will be necessary to identify all divided structures. It would be necessary to uncover the normal nerve a few centimeters above and below the point of injury and trace the divisions down to the site at which they were divided. It would be almost impossible to find the ends by dissecting directly in the scar of the wound. After these divisions have been isolated and after the tendons have been carefully inspected to determine whether or not any have been damaged, the blood pressure may be released and bleeding controlled. Following this, the pressure should be reapplied and the nerve and tendon repair performed. The nerves must be sutured with the finest

silk on atraumatic needles, accurate proximation of the nerve ends being obtained by careful suture of the perineurium without perforating the nerves with the needles.

Following operation, splints should be applied to keep the sutured nerves and tendons in a relaxed position, also to keep the paralyzed interossei relaxed. This means flexion of the wrist and of the metacarpophalangeal joints. Splinting of the wrist should be kept up for a period of three weeks and of the metacarpophalangeal joints for several weeks or months longer, until some evidence of regeneration occurs in the interossei.

If well carried out, this procedure should result in sensory return over the area of distribution of the ulnar nerve within three or four months. The motor return and disappearance of atrophy will take a longer time, and the chances of return of motor function are not so great as those of sensory return. There is no question that repair should be attempted.

DEATH FROM EXHAUSTION OF BODY RESERVE

To the Editor:—I am asking for an opinion on the question as to whether or not it is generally accepted in scientific circles that an organism can expire for lack of further body reserve. At a staff meeting of the members of a small hospital, the medical division reported two deaths. One was a case of influenza pneumonia in a patient with chronic asthma. The medical division, because of the speed with which the patient died, in spite of energetic treatment, concluded that the adrenal glands had become exhausted in an effort to keep the patient in physiologic balance during the paroxysms of asthma, which extended over a long period of time. This explained the inability of the patient to respond to treatment. The surgeons denied the possibility of this phenomenon. The second patient had chronic diabetes, developed gangrene of the right foot and leg, and died three days after the leg was amputated. When the patient was admitted to the hospital, in the presence of gangrene, the urine was negative for sugar, it had a specific gravity of 1.008, the twenty-four hour output was 13 ounces (385 cc.), the blood sugar was 342, and there were no signs of acidosis or alkalosis. On a milk and orange juice diet with insulin, the urinary output increased by 8½ ounces (250 cc.) in twenty-four hours but the specific gravity remained at 1.008. After forty-eight hours the leg was amputated under spinal anesthesia. The blood pressure dropped from 170/130 to 90/60 during the operation. Under small doses of epinephrine it went back to 130/90. Twenty-four hours later it was back to 170/120, with no change in the urinary picture except incontinence. The patient died seventy-two hours after operation. At no time prior to her death did she go into coma, nor was there any mental cloudiness. Her only complaint was a little pain in the stump. Four hours before her death she was seen by a member of the medical staff and was found to be in fair condition. Shortly after his visit, nourishment was refused with the statement that she was not hungry. She eventually grew drowsy and died almost suddenly. The medical division contend that this patient died of exhaustion, in the sense that all the kidney reserve had been used up and she could no longer avail herself of the medical treatment that was given. The surgeons hold such a phenomena to be impossible. Because of lack of laboratory facilities and a regular pathologist and technician, blood chemistry could not be done with the frequency which this case demanded.

LAWRENCE GREELEY BROWN, M.D., Elizabeth, N. J.

ANSWER:—Whether the patient with asthma and pneumonia died from exhaustion of the adrenal cortex cannot be determined, but the possibility that such exhaustion played a part in the outcome certainly cannot be denied. In the second case the question arises as to just what is meant by "kidney reserve." The symptoms as described do not suggest suppression of the urinary secretion. Speaking generally and from a theoretical point of view, it seems quite obvious that death may result from any condition which interferes with the adequate production and availability of any element essential to life. The function of the adrenal cortex, for instance, is vitally necessary. The exact mechanism at work in a given case may be difficult to analyze and beyond definite explanation.

USE OF BISMUTH COMPOUNDS IN SYPHILIS

To the Editor:—In the treatment of primary syphilis I frequently find it impossible to give a continuous biweekly course of bismuth therapy. Will bismuth compounds given at weekly intervals be as effective as those given two or three times weekly? Is the oil suspension of an insoluble salt better than the aqueous solution? What are considered to be the most effective in answer to these two questions and who are the manufacturers? Finally, what is your opinion of bismuth sodium tartrate 3 per cent Searle? Please omit name.

M.D., Alabama.

ANSWER:—Yes, there are certain bismuth preparations given at weekly intervals that will be as effective as a preparation used two or three times a week. For this purpose, naturally, it will be necessary to use an oil suspension of an insoluble salt rather than an aqueous solution. Thereby there is a slower absorption from the deposits in the muscles of the buttocks. As the result of this, of course, the level of bismuth in the blood stream may be a little slower in reaching the therapeutic height that is necessary, but once it is attained it will continue longer.

Where one desires to get a rapid bismuth effect, it probably is preferable to use one of the so-called aqueous solutions, for example, iodobismutol. This preparation seems to be intermediary between the true aqueous solution, an example of which is bismuth sodium tartrate, and the so-called liposoluble solutions, examples of which are bismo-cymol and biliposol.

Bismuth sodium tartrate is a pure aqueous preparation. To attain the proper therapeutic level in the blood stream, this preparation should be administered three times a week.

If one is going to use a preparation that will do the work through an injection but once a week, the liposoluble preparations may be chosen, for example bismo-cymol in a dosage of 2 cc. once a week or biliposol likewise in a dosage of 2 cc. once a week. Both preparations, however, are quite expensive, particularly the latter. An inexpensive bismuth oil suspension is the bismuth subsalicylate, which is made by several of the manufacturers in this country. The level of bismuth in the blood stream is somewhat slow in attaining the therapeutic height that is necessary for treating syphilis. Thus it probably will be well with the last two injections of a course of arsenicals to give the first injection of the bismuth salicylate. In this way when the course of bismuth injections between the courses of arsenicals is really instituted there would already be a therapeutic level of bismuth in the blood stream.

DERMATITIS FROM FISH

To the Editor:—I have been treating cases of "fish poisoning," a skin disease which follows repeated contact of the forearms and hands with fish. The lesions look exactly like a rather mild case of poison ivy dermatitis, there rarely being much weeping. Is there any special treatment indicated in these cases? Astringent lotions seem to give the best results, but I am anxious to find a specific—possibly a desensitizing-agent.

M.D., California.

ANSWER:—Possibly the dermatitis referred to is erysipeloid, a mild infection occurring frequently in those who handle fish. It was described in THE JOURNAL, July 25, 1936, page 302. Fishermen suffer frequently from stings from the poisoned spines found on many fish or from the poison secreted in the glands of many aquatic animals. Not only do these cause stinging directly but their flesh, dried and powdered as it may be in drying nets, sometimes causes sneezing and dermatitis. Another source of dermatitis in fishermen is the rubbing of oilskins, particularly on the wrists in cold weather.

See White, R. P.: The Dermatogoses, ed. 4, London, H. K. Lewis & Co., 1934, pages 377 and 405.

CHLORINATION OF WATER SUPPLY

To the Editor:—During the drought of 1934 this city began using chlorine in its water supply. The first three days it was so strong with chlorine that goldfish and flowers were killed, and many cases of gastroenteritis were caused. The board of health said that such amounts of chlorine were disagreeable but harmless. Because of low water supplies, the chlorine in the city water is again so heavy that when a pail is drawn it can be plainly detected several feet distant. A quantity drawn and allowed to stand eight hours is still so strong that it smells like a chloramine solution. Is such water fit for drinking and household purposes? To be fit for drinking and yet kill typhoid germs, need water contain more chlorine than is barely detectable by smell?

J. A. GUTHRIE, M.D., Neosho, Mo.

ANSWER:—The description of the existing conditions indicates that chlorine was applied to the water supply only as a temporary precaution. For that reason the method of application was no doubt crude and the control exercised over the dosing apparatus was probably manual in nature. The germicidal dose of chlorine varies from approximately 0.05 to 0.5 parts per million of water by weight, so that in a city with an estimated half million gallon daily water consumption it would require an expensive apparatus to control accurately the application of such small amounts of chlorine to the water supply. The probability is that the water supply was overdosed with chlorine from the fact that flowers and goldfish were killed in this water. Generally speaking, it is not necessary to have enough chlorine in water so that it is detectable by either odor or taste in order to kill typhoid or other water-borne disease organisms. There is an exception to this when water contains phenolic or other organic wastes that combine with chlorine to form the disagreeable "chlorophenolic" tastes. The amount of chlorine necessary to kill organisms changes with each different water supply, depending on the temperature of the water and quantity of adsorptive organic material present. The amount of chlorine may be made far in excess of the usual amount quoted without danger of toxic effect when ingested. However, such excessive chlorination produces a poor water supply from the standpoint of tastes and odors. Careful laboratory control is necessary if a safe, palatable water is to be produced at all times.

MILD INFECTION SIMULATING SYPHILIS
OR SCLEROSIS

To the Editor:—A white woman, aged 38, Lithuanian, a housewife, was referred to the hospital with a chief complaint of intermittent pounding parietal headaches and vomiting of three days' duration. There was also some associated loss of weight. She had felt quite well until the onset of her chief complaint. She has always enjoyed good health, without miscarriages or stillbirths. She has been married eighteen years and has four children living and well. Her husband was treated for syphilis four years ago. He had a venereal disease which might have been primary syphilis eight years before marriage. He now has a four plus Wassermann reaction. All the children have negative Wassermann reactions and have no stigmas of congenital syphilis. Under the classification of symptoms referable to the various systems there is nothing significant in a positive way. There is no soreness of the tongue. There are some drawing pains in the arms suggestive of paresthesia. No paresthesia is present in the lower extremities. The patient has no difficulty in walking. Urinary disturbances are absent. The patient is fairly well nourished; she appears somewhat anemic. Examination of the head and neck and of the cardiorespiratory and gastro-intestinal systems showed nothing significant. The blood pressure is 130 systolic, 90 diastolic in both arms. Neurologic examination showed the following significant manifestations: Babinski reflex negative. Ankle clonus as well as patellar clonus positive on both sides. Knee jerks exaggerated. Biceps and triceps also hyperactive. The pupils and eyegrounds were normal. There was some slight diminution in bone conduction in the lower extremities. No sensory disturbance could be elicited. Laboratory examination showed white blood cells 7,200, red cells varying from 3,000,000 to 4,500,000, color index 1, hemoglobin varying from 60 to 70 per cent. No deviation from the normal occurred in the appearance of the red blood cells. The Kahn and Wassermann reactions on the blood were negative on three occasions reported by two different laboratories. A provocative Wassermann test with reports from our own laboratory showed a persistently negative result (the technic of the provocative test was to give 0.3 Gm. of neoarsphenamine intravenously and take a blood Wassermann test daily over seven days). The spinal fluid Wassermann test done on two different specimens of fluid showed 80 lymphocytes the first time and 30 the second time. Globulin and the colloidal gold curve were normal. A titrated spinal fluid Wassermann test done on both specimens was negative in all dilutions. The spinal fluid was examined by two different laboratories with the same report. Fractional gastric analysis showed absence of hydrochloric acid with an ordinary test meal and also absence of hydrochloric acid after the analysis was repeated with histamine stimulation. The progress of the case was as follows: After three days in the hospital, the vomiting stopped. The headaches persisted with only slight improvement during the entire two months stay in the hospital. There was no improvement after spinal puncture. She was discharged with very little difference in her condition except the cessation of vomiting. Now the following questions arise: Am I justified in excluding syphilis as the cause of this patient's illness in spite of the fact that the husband showed the presence of syphilis? With these observations am I justified in diagnosing this case a combined sclerosis associated with achylia? I would appreciate your impression in this case. Kindly omit name.

M.D., Pennsylvania.

ANSWER.—There seems no evidence in this case that the patient has ever had syphilis. Her acute illness may well have been an acute mild infection. An influenza producing a mild meningismus would be capable of producing paresthesia in the arms, exaggeration of the deep reflexes, ankle clonus and a descending pleocytosis in the spinal fluid. Further, such an acute infection is capable, temporarily, of abolishing free hydrochloric acid from the gastric juice. From this point of view the patient might be regarded as in no future danger. However, another gastric analysis should be done when the general health is good a month or two from now. If achylia is found, liver therapy should be given in view of the relatively high color index. If headaches continue to be present, an encephalogram should be made.

MAGNESIUM IN WATER

To the Editor:—For the past several weeks the water supply of this city has contained large amounts of magnesium in a free state. What physiologic effect will this magnesium have if large amounts of the water are consumed over a considerable period of time? What effect will it have with regard to kidney stones? I have been unable to find any information with regard to this matter in any book on physiologic chemistry. Numerous housewives have complained of the staining of clothes after ironing.

M.D., West Virginia.

ANSWER.—Good water work practice tolerates as much as 100 parts of magnesium per million parts of water. Quantities in excess of this are not regarded with apprehension because of any prospective injurious physiologic action but solely on account of the troublesome hardness of water so produced. This query notes that the magnesium is present in the water in a "free state." If this implies that magnesium is present as elemental magnesium, such is not likely to be the case, nor is magnesium oxide likely to be present. Magnesium is found in the water supply of many cities in the form of the sulfate, chloride, carbonate or bicarbonate. The industrial uses of magnesium as such, or in the form of its salts, has attracted no attention to any toxic properties, with the exception that

metal fume fever may be produced by magnesium oxide arising in connection with the manipulation of magnesium in the molten state. This metal fume fever is not a specific disease, since an identical form of the disease may be produced by zinc, copper and other metals. Magnesium when taken by mouth is to be rated as one of the least toxic of all minerals.

At present the production of renal calculi is attributed to abnormal states growing out of infection of renal tissues, such as pyelitis. Given this state, renal calculi may appear in the absence of any known extrinsic factor, such as high calcium or magnesium content in the water. The presence of such chemicals in water supplies is unlikely to produce a high frequency of renal calculi. It has been found from animal experiments that the entire elimination of magnesium from the diet leads to the death of the experimental animals within a few weeks. No proof is available that magnesium in drinking water supply may be regarded as a serious hazard to health. The hardness of such water is objected to by housewives and by industry because of the economic problems produced, none of which stand in direct relationship to health. Extensive information pertinent to this inquiry may be found in:

Newns, G. H., and Wilson, Reginald: *Mandelic Acid in Treatment of Pyelitis in Childhood*, *Lancet* 2: 1087 (Nov. 7) 1936.
Hinman, Frank: *Principles and Practice of Urology*, Philadelphia, W. C. Saunders Company, 1935, p. 631.

RINGWORM OF THE FEET

To the Editor:—Please outline the treatment or give me new ideas regarding the treatment of epidermophytosis (ringworm of the feet) other than the methods I have employed, which are gasoline soaking, sodium thiosulfate baths, Castellani's paint followed by 10 per cent ammoniated mercury ointment, Whitfield's ointment, various formulas containing iodine crystals, potassium iodide, salicylic acid, alcohol, or salicylic acid, benzoic acid phenol mixtures. My wife has had the condition for about two years and we have tried everything we know, including discarding all wool stockings, slippers, shoes, and the use of various proprietary ointments. The condition is localized usually in one area and consists mainly of a bullous formation. When the top layer is removed and the base is treated religiously for a few weeks, it greatly improves, but in a month or so the entire bulla with its attendant pain recurs. I am considering a resection of the entire bulla with some surrounding normal tissue. Do you think this advisable?

M.D., New Jersey.

ANSWER.—The presence of a recurrent bullous lesion in a fixed location, as described, suggests the possibility of a traumatic or pressure factor in its production. A maladjustment in the mechanics of the foot might be one of the underlying factors in the production of the lesion. The epidermophytosis in this instance could well occur as a secondary, superimposed infection. Orthopedic care should be instituted before undertaking the surgery described.

Further local treatment may consist of applications of 10 per cent silver nitrate to the base of the bulla and daily painting of the area with a 3 per cent aqueous solution of gentian violet.

A description of the treatment of ringworm of the feet, by Wise and Wolf, appeared in *THE JOURNAL*, Oct. 3, 1936, page 1127.

SOFTENING OF NAILS

To the Editor:—A man, aged 39, in perfect health, with physical examination, including the usual laboratory tests, essentially negative, shows nails on the fingers and toes without their regular hornified appearance and soft and not distinct from the skin. He is losing the hair on his head, eyelashes, and eyebrows, and some of his beard is coming out. He is also becoming prematurely gray. This process dates back five years, slowly but progressively getting worse. Slides and cultures taken from these areas of hair are negative for fungi. This must be a definite disease, but I do not know the diagnosis or whether there is any treatment for it. Please give me some information regarding this condition.

M.D., Texas.

ANSWER.—An endocrine disturbance might be responsible, though none is known that presents exactly this syndrome. In the hope of finding some basis for such a diagnosis, an expert in the diseases of the endocrine glands should examine the man.

Another possibility, and by far the more probable, is that the change is due to a congenital defect. That it appeared at the age of 34 is no guaranty against its being congenital, for other defects of congenital origin appear during adult life. Cases of congenital defects of the hair and nails have been reported since 1872, and in some of these reports whole families defective in these appendages have been described. Other cases have been without familial occurrence. Some have been associated with other defects, such as webbed fingers or epidermolysis bullosa. There is no treatment known that would be likely to restore the hair or nails.

KANSAS: Topeka, June 15-16. Sec., Board of Medical Registration and Examination, Dr. C. H. Ewing, 609 Broadway, Larned.

KENTUCKY: Louisville, June 9-11. Sec., State Board of Health, Dr. A. T. McCormack, 532 W. Main St., Louisville.

LOUISIANA: New Orleans, June 3-5. Sec., Dr. Roy B. Harrison, 1507 Hibernia Bank Bldg., New Orleans.

MAINE: Augusta, July 6-7. Sec., Board of Registration of Medicine, Dr. Adam P. Leighton, 192 State St., Portland.

MARYLAND: *Medical (Regular)*. Baltimore, June 15-18. Sec., Dr. John T. O'Mara, 1215 Cathedral St., Baltimore. *Medical (Homeopathic)*. Baltimore, June 8-9. Sec., Dr. John A. Evans, 612 W. 40th St., Baltimore.

MASSACHUSETTS: Boston, July 13-15. Sec., Board of Registration in Medicine, Dr. Stephen Rushmore, 413-F State House, Boston.

MICHIGAN: Ann Arbor and Detroit, June 9-11. Sec., Board of Registration in Medicine, Dr. J. Earl McIntyre, 202-204 Hollister Bldg., Lansing.

MINNESOTA: Minneapolis, June 1-2. Sec., Dr. J. J. Hall, University of Minnesota, Minneapolis. June 15-17. Sec., Dr. Julian F. DuBois,

350 St. Peter St., St. Paul.

MISSISSIPPI: Jackson, June 23-24. Asst. Sec., State Board of Health, Dr. R. N. Whitfield, Jackson.

MISSOURI: St. Louis, June 3-5. State Health Commissioner, Dr. H. F. Parker, State Capitol Bldg., Jefferson City.

MONTANA: Helena, Oct. 5-6. Sec., Dr. S. A. Cooney, 205 Power Block, Helena.

NEBRASKA: Omaha, June 8-9. Dir., Bureau of Examining Boards, Mrs. Clark Perkins, State House, Lincoln.

NEW HAMPSHIRE: Concord, Sept. 9. Sec., Board of Registration in Medicine, Dr. Fred E. Clow, State House, Concord.

NEW JERSEY: Trenton, June 15-16. Sec., Dr. James J. McGuire, 28 W. State St., Trenton.

NEW MEXICO: Santa Fe, Oct. 11-12. Sec., Dr. Le Grand Ward, Sena Plaza, Santa Fe.

NEW YORK: Albany, Buffalo, New York and Syracuse, June 28-July 1. Chief, Professional Examinations Bureau, Mr. Herbert J. Hamilton, 315 Education Bldg., Albany.

NORTH CAROLINA: Raleigh, June 21. Sec., Dr. Ben J. Lawrence, 503 Professional Bldg., Raleigh.

NORTH DAKOTA: Grand Forks, July 6-9. Sec., Dr. G. M. Williamson, 4½ S. 3rd St., Grand Forks.

OHIO: Columbus, June 1-4. Sec., State Medical Board, Dr. H. M. Platter, 21 W. Broad St., Columbus.

OKLAHOMA: Oklahoma City, June 9-10. Sec., Dr. James D. Osborn Jr., Frederick.

OREGON: *Medical*. Portland, June 15-17. Sec., Dr. Joseph F. Wood, 509 Selling Bldg., Portland. *Basic Science*. Corvallis, July 17. Sec., State Board of Higher Education, Mr. Charles D. Byrne, University of Oregon, Eugene.

PENNSYLVANIA: Philadelphia and Pittsburgh, July 6-10. Sec., Board of Medical Education and Licensure, Dr. James A. Newpher, Education Bldg., Harrisburg.

PUERTO RICO: San Juan, Sept. 7. Sec., Dr. O. Costa Mandry, Box 536, San Juan.

RHODE ISLAND: Providence, July 1-2. Chief, Division of Examiners, Mr. Robert D. Wholey, 366 State Office Bldg., Providence.

SOUTH CAROLINA: Columbia, June 22. Sec., Dr. A. Earle Boozer, 505 Saluda Ave., Columbia.

SOUTH DAKOTA: Rapid City, July 20-21. Director of Medical Licensure, Dr. B. A. Dyar, State Board of Health, Pierre.

TENNESSEE: Knoxville, Memphis and Nashville, June 17-18. Sec., Dr. H. W. Qualls, 130 Madison Ave., Memphis.

TEXAS: Austin, June 21-23. Sec., Dr. T. J. Crowe, 918-19-20 Mercantile Bldg., Dallas.

UTAH: Salt Lake City, June 21-23. Dir., Department of Registration, Mr. S. W. Golding, 326 State Capitol Bldg., Salt Lake City.

VERMONT: Burlington, June 16-18. Sec., Board of Medical Registration, Dr. W. Scott Nay, Underhill.

VIRGINIA: Richmond, June 17-19. Sec., Dr. J. W. Preston, 23½ Franklin Road, Roanoke.

WASHINGTON: *Basic Science*. Seattle, July 8-9. *Medical*. Seattle, July 12-14. Dir., Department of Licenses, Mr. Harry C. Huse, Olympia.

WEST VIRGINIA: Fairmont, July 12. Sec., Public Health Council, Dr. Arthur E. McClue, State Capitol, Charleston.

WISCONSIN: *Basic Science*. Milwaukee, June 5. Sec., Prof. Robert N. Bauer, 3414 W. Wisconsin Ave., Milwaukee. *Medical*. Milwaukee, June 29-July 2. Sec., Dr. Henry J. Gramling, 2203 S. Layton Blvd., Milwaukee.

WYOMING: Cheyenne, June 7. Sec., Dr. G. M. Anderson, Capitol Bldg., Cheyenne.

NATIONAL BOARD OF MEDICAL EXAMINERS SPECIAL BOARDS

Examinations of the *National Board of Medical Examiners and Special Boards* were published in THE JOURNAL, May 22, page 1825.

California February Examination

Dr. Charles B. Pinkham, secretary, California State Board of Medical Examiners, reports the written examination held at Los Angeles, Feb. 9-11, 1937. The examination covered 10 subjects and included 90 questions. An average of 75 per cent was required to pass. Thirty-six candidates were examined, 33 of whom passed and 3 failed. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
University of Arkansas School of Medicine.....	(1936)	87.3	75.9

Book Notices

A Key to the Rattlesnakes with Summary of Characteristics. By Laurence M. Klauber, Curator of Reptiles and Amphibians, San Diego Society of Natural History. Transactions of the San Diego Society of Natural History. Volume VIII, No. 20. Printed for the Society. Paper. Price, \$1. Pp. 185-276, with illustrations. San Diego, California, 1936.

Mr. Klauber, qualified by an unprecedented experience as curator of reptiles and amphibians of the San Diego Society, handles his subject as a thorough scientist in describing species and subspecies of rattlesnakes, with a summary of their individual characters, a key for specific determinations, and life history data, of great advantage to the student. He feels a sneaking sympathy with the rattlesnake genus, which is not aroused by the moccasin.

With the appearance of this work there comes naturally to mind the fine works of the herpetologist Dr. J. E. Holbrook of Charleston, S. C., in the early forties, and especially that of Dr. S. Weir Mitchell, whose world-wide reputation rests in part on his "Researches upon the Venom of the Rattlesnake" (Smithsonian Contributions to Knowledge, 1860). Nor should one forget the great taxonomy of E. D. Cope of Philadelphia (Smithsonian Institution, 1900). Among recent authorities are the late John Van Denburgh of San Francisco, Alexander G. Ruthven and Frank N. Blanchard of the University of Michigan, A. I. Ortenburger of the University of Oklahoma, and our present-day therapist in the snake venom field, Dr. Dudley Jackson of San Antonio.

Touching the various kinds of rattlesnakes, Klauber, including all their habitats, finds a total of forty species and subspecies. Stejneger and Barbour in their authoritative "Check List of North American Amphibians and Reptiles," 1923, list twenty-one, six of which are from Lower California; since then five subspecies have been described and two others revived. Klauber deletes from the confusing literature many synonyms, among them *kellyi*, named by Do Amaral (1929), chief of the antivenin snake farm at São Paulo, Brazil. The South American *Crotalus terrificus* appears as a subspecies of *Crotalus durissus*; it is the most dangerous of all the crotalids as well as the most virulent, because of the large amount of neurotoxin in its venom, in which it resembles the cobra group. In going over Klauber's data, one realizes how difficult the readjustments have been. The thirty-eight rattlesnake photographs which he presents are valuable aids in identification and are unsurpassable, as are the fine line drawings and the maps of territorial distribution. There is also a complete glossary of value to the nonspecialist.

Of great interest to doctors is the question of the poisonous snake bite and its treatment. In the first place, North American rattlers do not pursue their victims but are generally anxious to make their escape, which is relatively slow because of their heavy build as compared with the harmless blacksnakes and coachwhips. It sometimes happens that in going through the woods one steps across a log close to a rattlesnake which does not stir. Sometimes a badly scared complainant has not been bitten by a snake but merely scratched by thorns. Klauber emphasizes the fact not generally known that the poison of some species is far more toxic than that of others, stating that "There are considerable differences both in toxicity and in physiological effects in the venoms of several rattlesnake species, some being sixty times as powerful drop for drop as others. Some are primarily hematoxic; others neurotoxic." The yield of venom per snake varies greatly according to the species, even in snakes of similar size, and is voluntarily controlled. The following are a few adult averages, the figures representing the yield of one milking in milligrams of dried venom: *C. cinereus*, 270; *C. v. oreganus*, 140; *C. m. mitchelli*, 33; *C. cerastes*, 32; *C. tigris*, 11. A general but not universal rule is that rattlers which give low quantitative yields proportionate to their size have the most powerful venoms. The maximum recovery from a single snake was from *C. cinereus*, the large Texas snake that has been called *atrox*, which yielded 1,145 mg. of dried purified venom, the largest amount secured from any of the 4,000 rattlers milked by Klauber.

When a child is bitten, it receives a dose of venom larger than an adult, proportionate to the difference in size and body

weight; this also explains why small animals die so quickly. Death takes place from the poison absorbed and carried up into the body. Agreeing with others, Klauber reckons that only about one in ten persons would die if they had no treatment; but he states that the death rate is higher with some especially dangerous species, among which the big Florida diamondback must certainly be included.

Fourteen variable factors in snake bite are listed.

A man, fortunately, is usually struck below the knee or on the forearm or hand, making it much more convenient for treatment. The wound is immediately followed by severe local pain with marked swelling due to hemolysis; the fang punctures are readily distinguished. To allay excitement and rash acts, the author adds "Remember that few cases of rattlesnake bite are fatal."

The first injunction is to avoid foolish or harmful remedies. Alcohol is harmful and never helpful; patients sometimes die from an excessive dosage of whisky. Potassium permanganate, carried by so many hunters into the field in little bottles along with a hypodermic syringe, never helps in the least, while it produces frightful sloughs, of which alone patients have died long after the bite. Cauterization is useless, and the madstone is foolish. There is just one rational, simple remedy; namely, to keep the poison localized and to get it out of the tissues where it is localized, as speedily as possible, by suction. This is the oldest remedy, imperfectly applied by mouth by Indians and peons with indifferent success but brought to great perfection by Dudley Jackson of San Antonio after extensive experimentation. For example, as but one of a long series of experiments, some of them conducted with Colonel Crimmins of the United States Army, a dog was injected in a hind leg with five times the lethal dose of rattlesnake venom, which is a milligram per pound. With incisions and suction, Dr. Jackson withdrew what was recoverable and with that injected four other dogs. Two of these died and two others with terrible slough were killed; the first dog, receiving the excessive amount, recovered. Dr. Jackson also found that a number of victims both human and animal had gas gangrene, calling for amputation or the removal of large areas of necrotic tissue. The organism *Bacillus welchii* was located in the fangs and venom of the rattlesnake!

He who goes afield in a rattlesnake country should wear stout leather leggings and carry a small pocket kit containing rubber tubing to encircle the limb above the swelling and cut off circulation, a small bottle of an antiseptic (iodine), a sterile razor blade in a little bottle, and a cup and suction bulb. Such kits are supplied by the Flack Company of San Antonio and by others. The ligature must not be too tightly applied (enough to control the lymphatic circulation) and should be released every fifteen or twenty minutes for one or two minutes. The whole area is painted with the antiseptic and the knife blade used to make crucial incisions, first through the skin and connective tissue at each fang puncture, followed by similar incisions about three fourths of an inch apart over the entire swollen area. The glass cup with the stout rubber suction bulb is set to work over each incision and the bloody fluid drawn off. This evacuation process must be persisted in for half an hour and repeated at intervals while there is any swelling. The ligature is moved up the limb if any swelling appears above it. It helps sometimes to inject a 2 per cent salt solution into the tissues to dilute and facilitate suction. The patient is of course placed under a doctor's care and taken to a hospital as soon as possible. Since a transfusion is occasionally called for, the blood should be typed promptly to avoid delay.

The field of usefulness for antivenin is likely to vary with the species involved. The two methods are not mutually exclusive. Antivenin has not been found effective in the Florida diamondback, *C. adamanteus*, and in the Texas *C. atrox* (*cinereus*). A serious difficulty lies in the cost of the considerable number of ampules that may be required.

Every physician in a rattlesnake country ought to own this work, which is interesting and readable and would seem destined to become a classic in its field. The author's hope in preparing this key is that it will be used by physicians unacquainted with herpetological classification, as an aid for proper identification of the various snakes involved in snake bite cases, thus building up dependable case records. Heretofore it has been deemed sufficient merely to report the animal offender as a "rattlesnake."

Röntgenbiologische Untersuchungen mit Gewebekulturen als Indikator. Von Børge Faber. Paper. Pp. 119, with 12 illustrations. Copenhagen: Levin & Munksgaard, 1935.

The author has endeavored to find expression for the rules of biologic effects of x-rays under different conditions. Normal tissue cultures have been used as a biologic measure-factor for this purpose. He first gives a brief report of the biologic units of measure now ordinarily employed. He then discusses the adaptability of tissue culture for this purpose, giving in detail the technic employed. The histology of normal fibroblast cultures is described and reference is made to a series of examinations of the cultures. The experiments show variations in the rate of growth in different cultures in such a way that some cultures which during the experiment grow more quickly than others continue to grow more quickly during the entire experiment. The velocity of growth of the single culture from day to day shows furthermore regular oscillations, caused by different external conditions (nutrition). If a comparison of growth is made in periods in which the cultures have the same external conditions, the velocity of growth is constant.

In experiments with irradiation the author describes the normal microscopic and macroscopic changes after the irradiation and after a series of examinations of the dependence of the effect of the rays on the ray quantity. Through these experiments it has been proved that the x-ray effect is a retardation effect which varies with the particular x-ray quantity. Doses under 200 roentgens do not cause any definitely proved retardation. The latest period for the x-ray effect is, under these circumstances, about twenty-four hours. It has been impossible to discern any stimulating effect. The lethal dose is about 1,200 roentgens, which however requires about six or seven days to cause absolute cessation of growth, and even four or five times the lethal dose does not hasten the death of cultures.

The influence of the quality of the rays on the biologic effects of a particular x-ray dose was next examined. Care must be taken that the same absorption ratio obtains in the physical ionization chamber as in the biologic test object. In the main the results of the previous examinations agree with the present experiments in showing that the biologic effect is independent of the ray quality.

The influence of the time factor on the biologic effect of a particular x-ray quantity has been answered differently by previous examiners. The majority maintain that Bunsen-Roscoe's rule (i.e. equals k) is valid for resting tissues, while Schwarzschild's rule (i.e. t^p equals k) is valid for growing tissues. Some authors have, however, also found Bunsen-Roscoe's rule valid for growing tissues. In the present five series of experiments, the validity of Bunsen-Roscoe's rule for growing tissues has been proved.

Previous workers have concluded that increased cell activity is followed by increased radiosensitivity. According to the present investigation, where the cell activity during the irradiation and the cell activity after the radiation have been examined separately it seems that an alteration of cell activity during the irradiation is not followed by any detectable alteration of the ray effect on the tissues.

Measuring Health Needs in an Urban District. By Dorothy G. Wiehl. Reprinted from *The Milbank Memorial Fund Quarterly*, Vol. XIV, Nos. 1, 2, and 4, January, April, and October, 1936. Paper. Pp. 57, with illustrations. New York: Milbank Memorial Fund, 1936.

District Health Administration: A Study of Organization and Planning. By Ira V. Hiscock, Professor of Public Health, Yale University School of Medicine. With a foreword by John L. Rice, M.D., Commissioner of Health, New York City. Published for the Milbank Memorial Fund. Paper. Price, 65 cents. Pp. 115, with 16 illustrations. Lancaster, Pennsylvania: Science Press Printing Company, 1936.

The measurement of the health needs in the Mott Haven District in New York as carried out by the Milbank Memorial Fund preceded the establishment of district health administration in greater New York. The pamphlet on measuring health needs is a reprint of articles appearing originally in the *Milbank Memorial Fund Quarterly* and representing studies of 1,049 families in the Mott Haven District, the Bronx, New York. The material should be of interest to physicians and public health workers, especially in view of the conclusion; namely, "lack of income was associated with the failure to obtain medical care, especially in the case of acute conditions; persons with diseases of an organic nature were attended at least as fre-

quently in poor families as in those with slightly higher incomes." "One half of the illnesses which received any care had had some free or part-pay care." The pamphlet on district health administration arises out of the extensive studies by Professor Hiscock in health administration in cities, counties and metropolitan districts. It deals mainly with the decentralization plan of health department administration developed in New York City. Reference is also made to some other health centers. While the author has a clear conception of the importance of the practicing physician in health programs, his study of health centers, nevertheless, brings out the fact that this development, while highly desirable from the administrative point of view, shows definite dangers of trends toward competition by health departments with practicing physicians. District health centers are undoubtedly a necessity from the administrative standpoint in great cities and are a logical outcome of the district or community character of these cities. If properly carried out, such decentralization should have a favorable effect both on health administration and on medical practice, but it will be necessary for physicians to keep fully informed as to developments in district health administration.

Illustrations of Regional Anatomy. By E. B. Jamieson, M.D., Senior Demonstrator and Lecturer, Anatomy Department, University, Edinburgh. Section VI: Upper Limb; Section VII: Lower Limb. Paper. Loose-leaf. Price, \$2; \$3; \$14, per set of 7 sections, 42 plates; 52 plates. Baltimore: William Wood & Co., 1936.

Sections VI and VII complete the set of "Illustrations of Regional Anatomy" prepared by Dr. Jamieson. These two are devoted to the extremities, the rest of the body having been covered in sections I to V; in all they constitute a regional atlas of 297 plates. The drawings are based on blackboard sketches made by Dr. Jamieson in his lectures at Edinburgh, and these sketches were based in turn on special dissections made for those lectures. Colors are used abundantly and the plates are so bound that any one of them can be easily removed and replaced. Plates that are especially interesting because they represent structures and relations not so well shown in other atlases are those representing sections through the joints—elbow, wrist, knee, ankle and transverse tarsal (Chopard's joint). The relations in these interesting regions are well shown. Other plates show the mucous sheaths of tendons in the hand and foot especially well. Because of its regional character, this atlas is a valuable supplement to the systematic atlases of Toldt, Spalteholz and Sobotta, commonly used by American students.

Catalogue of the National Collection of Type Cultures Maintained by the Council at the Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W. Medical Research Council, Special Report Series, No. 214. Fourth edition. Paper. Price, 2s. 6d. Pp. 159. London: His Majesty's Stationery Office, 1936.

A list of the extensive collection of wood-destroying fungi, and fungi causing discoloration of timber belonging to the Forest Products Research Laboratory, Princes Risborough, Bucks., has been added. By special arrangement with the authorities of the Lister Institute for Preventive Medicine, of the National Institute for Medical Research, of the Veterinary Laboratory of the Ministry of Agriculture and Fisheries and of the Rothamsted Experimental Station, a list of filtrable viruses and of bacteriophages has also been included in this catalogue. Subcultures are obtainable by application to the curator, who will refer requests to the proper authorities of the corresponding institutions. The nomenclature adhered to in this volume accords in principle with the recommendations of the Nomenclature Committee of the International Society for Microbiology. The emendations in bacterial nomenclature suggested by the American systematists, as embodied in Bergey's Manual of Determinative Bacteriology, are entered in this volume in brackets after the names of bacteria concerned. The collections represented in the catalogue appear to be all embracing and down to date. The taxonomic position of the trouble-giving genus *Salmonella* has been investigated by a subcommittee of the Nomenclature Committee of the International Society for Microbiology. Its recommendations have been embodied in the catalogue. The nomenclature adopted however, remains unofficial until approved by the Nomenclature Committee itself. The following additional information

makes this catalogue of particular value to workers in the field of microbiology: reference number; particulars of the type, group or variety to which the strain belongs; name of the person from whom the strain was received; identification mark by which the strain has been known previously; particulars of the source from which the strain was isolated, and a short statement concerning some differentiating characteristics of the species or strain.

Studies In Infant Speech and Thought. Part I: The Development of Sentence Structure in Infancy from the Viewpoint of Grammar; A Quantitative Analysis of the Continuous Speech Record of Two Infants. By Abraham A. Low, M.D., Assistant Professor of Neuropsychiatry, University of Illinois. *University of Illinois Bulletin* Volume XXXIII, No. 39. Illinois Medical and Dental Monographs, Volume I, No. 2. Paper. Price, \$1. Pp. 71. Urbana, Illinois: University of Illinois, 1936.

"The main purpose of the present study was to evolve methods rather than to draw conclusions from the elaborated material." The primary object of this record is to work out a method that would show the language development of the child. This is a valuable type of study and it is apparently written with no thesis to prove but with an objective point of view. It is a highly technical study in monograph form with many valuable charts and tables. It is modestly stated, which perhaps is not so usual in monographs but that it might be mentioned. It is the study of the observations of two mothers of their two children, one a boy 1 year and 4 months of age at the beginning of the study and the second a child of 2 years and 8 months. In the study of the first child, 4,500 utterances were recorded and 3,815 analyzed. In the speech of the second child 8,000 were recorded and 3,190 analyzed. There is a question whether these are typical language responses, because the very act of being observed to the point of recording doubtless had put considerable emphasis on speech, which might easily cause it to develop atypically. This is a splendid study, and although it makes no effort at an analytic survey it does cover its own field well. Perhaps the writers will continue and enlarge this valuable type of study. It might be suggested that similar studies be made covering, of course for only a sampling period, the speech structure used by the adult members of the families of these children. Certainly in adults of the same approximate education, language structure differs materially. "Wanna go" might be commonplace in one well educated family and the full sentence structure be used in another. These deviations in the casualness of speech as against the formality of speech in the adults of the families might have had a definite influence on the speech of the children.

Kidney Pain: Its Causation and Treatment. By J. Leon Jona, D.Sc., M.D., M.S., Hon. Assistant Gynecological Surgeon, Women's Hospital, Melbourne. Cloth. Price, 7s. 6d. Pp. 94, with 61 illustrations. London: J. & A. Churchill, Ltd., 1937.

The object of this book is to bring before medical practitioners some views of the author on the causation of obscure kidney pain and its treatment. These ideas are the outcome of his own researches on the physiology of the kidney pelvis, both normal and pathologic. The approach has been from the experimental as well as the clinical side. The chief object has been to bring forward methods that may be used in attempting to elucidate the causation of obscure kidney pain when the ordinary methods of investigation have failed. These methods are pyeloscopy and pyelometry. Radiopaque fluid is injected through a ureteral catheter and the renal pelvis observed under the fluoroscope while the injection is being made; this method is called pyeloscopy. The term "pyelometry" is applied to the method of graphic recording of kidney contractions; variations in the volume of the renal pelvis indicate changes in the activity of the renal-pelvis musculature. The recording is accomplished by means of a special apparatus, which consists chiefly of a tambour carrying a writing point and connected with a ureteral catheter, filled with physiologic solution of sodium chloride. With these methods the author studied the action of various drugs on the renal pelvis and ureter. His experimental and clinical observations indicate the value of both methods, in conjunction with the ordinary pyelogram, as aids in arriving at a diagnosis in various obscure conditions causing pain in the kidney region. The booklet should be of great interest to every urologist.

Domestic Heating by Gas Considered from the Point of View of Health and Comfort. Report of an Advisory Committee Appointed by the College at the Request of the Governor of the Gas Light and Coke Company. Approved for publication by the Comilla of the College, July, 1936. Paper. Price, 1s. Pp. 31. London: Royal College of Physicians of London, 1936.

"This report is the outcome of the deliberations and investigations of a Medical Advisory Committee appointed with the approval of the Royal College of Physicians and at the request of the Governor of the Gas Light and Coke Company to consider problems arising out of modern developments in the use of gas for domestic heating and of changes in methods of building construction, with special reference to the significance to health and comfort of the use of flueless gas appliances in rooms unprovided with flues or other devices which promote ventilation." Quite aside from its scientific value, the pamphlet possesses a grace of phraseology and a precision of thought seldom encountered in modern medical literature. The report suggests that a study of the necessary air change in the ordinary bedroom or living room offers a desirable field of investigation, since this question has not been adequately considered. It suggests that such rooms, heated by gas, be provided with flues. It is pointed out that, under ordinary conditions, chemical changes in the air due to the use of gas for illuminating purposes is of no great importance under ordinary conditions. Of special interest to those interested in the prevention of asphyxial death is the finding that illuminating gas containing from 10 to 30 grains of sulfur oxide per hundred cubic feet automatically acts as a warning agent against the toxic effects of carbon monoxide. The view is also expressed that carbon monoxide is not cumulative in the sense that lead poisoning is cumulative, and that concentrations of 0.01 are well tolerated over long periods. (Under ordinary conditions of gas heated rooms, the concentration of carbon monoxide is approximately 0.005.) The possible carbon dioxide accumulation seldom exceeds 1 per cent maximum and is not regarded as serious. This pamphlet should be on file in all libraries where information relative to carbon monoxide poisoning may be requested.

Juvenile Paresis. By William C. Menninger, M.D. The Menninger Clinic Monograph Series No. 1. Cloth. Price, \$3. Pp. 199, with 16 illustrations. Baltimore: Williams & Wilkins Company, 1936.

This is the first monograph of a projected series from the Menninger Clinic and its excellence has set a standard of achievement which subsequent volumes will have difficulty in maintaining. The work is a complete treatise on juvenile dementia paralytica. It is well written, thoroughly documented from the literature and the author's own experience, and has an extensive and adequate bibliography. It is well illustrated and contains many easily read tables. The subject matter is exhaustively discussed in easily readable style. Rarely has a monograph accomplished its aim so successfully. Each chapter is summarized and from the numerous conclusions no serious divergence of opinion is possible in the light of our present evidence. The book should be of universal service to physicians.

Traité de thérapeutique clinique. Par Paul Savy, professeur de clinique médicale à l'Université de Lyon. In three volumes. Cloth. Price, 360 francs, per set. Pp. 2,734. Paris: Masson & Cie, 1936.

This system of clinical therapy will no doubt make a place for itself in the literature on therapeutics, for it has been written by a man with a great deal of clinical experience and it puts strong emphasis on the practical as contrasted with the theoretical. It is copiously interspersed with formulas. The pharmacodynamics of the important remedies is extensively discussed. Surgical indications, whenever present, are also carefully formulated. This excellent text and reference book may be unreservedly recommended to the physician who reads French.

Lehrbuch der Geisteskrankheiten. Von Oswald Bumke. Fourth edition. Paper. Price, 21 marks. Pp. 632, with 128 illustrations. Munich: J. F. Bergmann, 1936.

This is virtually a new work. The author has kept pace with the changing concepts in psychiatry and profited by the special work of his younger colleagues. Yet he ignores dynamic psychiatry and dismisses it as "awful nonsense" and perpetuates a modified kraepelinian descriptive psychiatry resting on an organic point of view. However, the volume remains one of the best psychiatric textbooks published.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Poisons: Injuries Attributed to Use of Eyelash Dye.—The plaintiff suffered painful and serious injuries as the result of the application of a preparation designed to darken eyebrows or eyelashes. She sued the Powder Box Beauty Shoppe, where the preparation was applied, and the manufacturer of it, the Ey-Tec Company, in the city court of New York, Kings County, but at the close of the trial the plaintiff consented to a dismissal of the case against the beauty shop.

The label affixed to the container of the preparation read as follows:

Non-Toxic Safe Lasting Ey-Tec contains no paraphenylenediamine, no aniline derivatives, no poisonous metals. It complies with all pure food and drug regulations. It requires no predisposition test. Ey-Tec may even be dropped into the eyes without harm, and may be used with absolute safety. Ey-Tec a product of Ey-Tec Co.—425 Fifth Ave.

It was testified that the substance of the statement appearing on the label was brought to the attention of the plaintiff before the preparation was applied and that she relied on the statement. It was undisputed that the Ey-Tec contained as active ingredients silver nitrate, ammonia and pyrogallol acid. A chemist for the plaintiff testified that the percentages of these ingredients found in the preparation were poisonous, harmful and dangerous for external use about the human face and especially in and about the eyes. The chemist for the manufacturer admitted the presence of the ingredients but contended that they were not present in such percentages as to make the use of the preparation dangerous. The manufacturer claimed to have sold a quantity of Ey-Tec without knowledge heretofore of a harmful result and to have tested the formula about and in the eyes of animals with no harmful results. In the opinion of the court, however, the plaintiff sufficiently connected her injuries with the application of the preparation. In *Karr v. Inecto, Inc.*, 247 N. Y. 360, 160 N. E. 398, the Court of Appeals of New York said:

Before the plaintiff may recover she must show, first, that the injury to the finger resulted from contact with the chemical product manufactured by the defendant; second, that the chemical product was inherently dangerous and poisonous; and third, that the defendant was negligent in putting upon the market a dangerous and poisoning product.

And, again:

If the evidence establishes that the liquid contained in the bottles of dye used by the plaintiff was dangerous and poisonous, then from the fact that the injury followed contact with the dye we might draw the inference that the injury was the result of that contact. In such case, too, we might without further evidence as to how these particular bottles happened to contain a dangerous and poisonous liquid infer that such a condition could not have arisen without fault on the part of the employees of the defendant.

In the present case, the court thought that all the elements mentioned in the opinion in the *Karr* case were present and that the same inference was warranted. Accordingly, the court entered judgment in the sum of \$2,000 for the plaintiff. A motion for leave to appeal was denied (288 N. Y. S. 1078).—*Bundy v. Ey-Tec, Inc.* (N. Y.), 289 N. Y. S. 905.

Workmen's Compensation Acts: Pulmonary Tuberculosis Attributed to Leg Injury.—An employee in 1930 sustained during the course of his employment an injury to the lower part of his left leg for which he was paid compensation. In 1934 the employee died of pulmonary tuberculosis and his widow applied to the department of labor and industries for a widow's pension, claiming that the original injury sustained by her husband had developed a tuberculous condition, which was the causal factor of death. The department rejected the claim on the ground that the death of the employee did not result from the leg injury. The superior court sustained the finding of the department, and the claimant appealed to the Supreme Court of Washington.

A physician who had known the employee for eleven years and who had treated him for his leg injury testified that an injury to any part of the body might possibly have a tendency

"to give place for the development of tubercular bacteria." He further testified, however, that although an injury to a part of the body might result in its devitalization, it would not have a tendency to localize a tubercular condition. The other physician who testified for the claimant had never seen the deceased employee. In response to hypothetical questions, he testified that, in the absence of other factors, he would attribute the death of the employee to miliary tuberculosis having its inception in the injury to the leg and finally localizing in the lung. He testified, however, that he could not positively say what was the direct cause of the employee's death.

In the opinion of the Supreme Court, there was ample evidence to justify a finding that the death of the employee, although caused by tuberculosis, was not the result of the injury to the leg. The judgment against the claimant was therefore affirmed.—*Mattson v. Department of Labor and Industries* (Wash.), 60 P. (2d) 248.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

American Journal of Anatomy, Philadelphia

Meeting the Needs of the Community. H. E. Thelander, San Francisco.—p. 1060.

Effect of Carbohydrate in Fatigue.—In order to determine the effect of the nutritional state on fatigue, Schlutz and Blish studied the changes in the acid base balance and in the sugar content of the blood after exercise on sixteen children between the ages of 8 and 13 years. The effects of exercise were observed in the fasting state and after the ingestion of various sugars, principally dextrose and levulose. Fourteen of sixteen subjects who exercised during fasting showed increase in fixed acid after fifteen minutes of exercise. The response of the asthenic child to the fixed acid produced was not uniformly unlike that of the normal child, but differences were seen in the samples taken at exhaustion. The normal child showed a lower value for fixed acid at the peak than did the asthenic child. This tends to indicate a greater improvement in oxygen transport and therefore a quicker response for the delay of fatigue. When sugar was given just before exercise, six of the sixteen children showed that the entrance of fixed acid was inhibited after fifteen minutes or at exhaustion, and in many experiments in which this change was not seen there was a more abrupt drop in the curve toward exhaustion when sugar had been given. Three of four children who were given sugar one-half or one hour before exercising showed a more rapid effect on the depression of fixed acid than was seen when sugar was given simultaneously with exercise. The ability to store sugar improved with exercise, as indicated by the depressed curve for sugar in the blood during the period of exercise. Training further increases the efficiency of the mechanism for glycogen storage as well as that for oxygen transport. Lactose and sucrose had no inhibiting effect on

the rise in the level for fixed acid during exercise in the subjects studied. In all subjects studied, exercise produced a depression in the curve for sugar as determined with the same amount of sugar without exercise.

Hypoglycemia of Childhood and Recurrent Convulsions.—A study of eleven cases of hypoglycemia associated with recurrent convulsions, together with a review of the reports previously contributed, suggests to Rector and Jennings that among infants and children hypoglycemia is usually a functional hepatic disorder of intermittent character, resulting from a temporary depletion of the glycogen reserve. In most cases the condition is amenable to conservative management, and the prognosis is infinitely better than it is for older patients with hypoglycemia, which is often organic. While hypoglycemia is undoubtedly not a frequent cause of convulsions in childhood, continued emphasis on the desirability of making studies of the blood sugar in all cases of obscure convulsive disorders may demonstrate a current incidence greater than is now accepted.

Chronic Diffuse Mesenteritis: Report of Two Cases of Unusual Type. E. E. Sproul and J. J. Hawthorne, New York.—p. 311.

Coarctation of Aorta with Occlusion of Superior Vena Cava.—While conforming to the usual picture of aortic coarctation in respect to age, sex, the bicuspid aortic valve, development of collateral circulation and notching of the ribs, the case that Benkwitz and Hunter report differs sharply from nearly all others studied heretofore in that there occurs both an infantile and an adult type of coarctation. The coexistence of infantile and adult coarctation lends support to the hypothesis of Craigie that the basis of the anomaly lies in an embryologic disturbance of formation and involution of the primitive aortic arch. Another observation that makes the case differ from the group of aortic coarctation is the concomitant occlusion of the superior vena cava and its innominate tributaries, necessitating the development of a venous collateral return for the head, neck, upper extremities and thorax fully as extensive and intricate as the aortic coarctation demanded of the arterial circulation in order that the abdomen, lower extremities and most of the thorax might receive arterial blood. Thus, of necessity, over the torso both the arterial and the venous blood flowed caudally and in parallel vessels. The only possible clue as to the cause of the fully organized and canalized thrombosis of this vessel is that in conjunction with the pericarditis or pleuritis there may have been a thrombophlebitis of the superior vena cava and its tributaries. Contributing to the final cardiac decompensation was not only the coarctation of the aorta but the healed pericarditis and pleuritis binding the contents of the thorax to the wall of the chest and the diaphragm, thus throwing an additional load on the already burdened heart. In conjunction with the bicuspid aortic valve was a calcified ring which may be classed as a subaortic stenosis, an uncommon yet clinically important cardiac lesion. The case illustrates the ability of the circulatory system to compensate for obstructions of even major vessels and the reserve strength of the heart which withstood not only the

coarctation but also, prior to the last attack, the toxic effects of pneumonia and empyema and carried the increased load occasioned by the adhesive pericarditis and pleuritis for an indefinite period.

Carrier-Borne Typhoid in New York State.—Stebbins and Reed point out that 570 chronic typhoid carriers have been declared in New York State from 1911 through 1935. Exclusive of fifty-nine carriers discovered in state institutions, 72 per cent of all carriers were discovered by epidemiologic investigation of sporadic cases of typhoid. The incidence of typhoid among the household contacts of carriers was found to be forty-two times that in the general population. The ratio of cases to carriers before and after discovery was significantly different, entirely as the result of a high ratio in the first ten years of "carrier age" before discovery. The attack rates among unvaccinated household contacts of carriers was studied by means of "exposure age" and "carrier age." The attack rate among unvaccinated household contacts of carriers was found to be five times that of vaccinated contacts.

Acute Lymphangitis.—Steel believes that acute lymphangitis involves, simultaneously, the superficial lymph vessels and glands and might be better termed acute lymphangio-adenitis. Serious infections follow trivial skin wounds in those whose occupations predispose to skin soiling with infected material; i. e., doctors, nurses, laboratory technicians, undertakers or persons with diabetes. The red skin line running from a skin wound to the nearest tender lymph node is the primary symptom. The serious case shows rapid spread of local signs within two to six hours and a chill within the first thirty-six hours.

The lymph nodes involved are fairly consistent in infections of the different body areas. A differential diagnosis between acute lymphangio-adenitis and acute thrombophlebitis is outlined. Primary local treatment is directed toward assisting those natural processes which the body calls forth to combat infection; i. e., rest, large wet hot compresses and no local meddlesome surgery. The treatment of the sequels—palmar abscess, localized glandular abscess, diffuse purulent cellulitis and septicemia—is presented. Blood transfusion is the most reliable agent for septicemia, assisted by saline solution hypodermoclysis and dextrose solution intravenously. In palmar abscess the recommendation is clean cut incisions in the palm and above the wrist, wet dressings, no drains, Bier's passive hyperemia by an elastic bandage to the upper arm every two hours for two hours, soaking the hand in hot saline solution fifteen minutes between the rubber bandage applications, and squeezing the pus out gently through the incisions twice daily. In localized glandular abscess when superficial fluctuation is present, the abscess should be opened by a simple incision without retraction, curettage or digital exploration. The wall of leukocytes and fibroblasts surrounding the now functionless glands is nature's limiting wall against further entry of infectious matter into the systemic circulation and should not be broken down. For diffuse purulent cellulitis, simple incisions are to be made over each fluctuating area as it presents itself.

Treatment of Boils.—Gordon believes that the greatest adjunct to the treatment of boils and carbuncles is eradicating autoinfection. A lesion that is not draining and the size and depth of which preclude the use of emplastrum salicylate Klotz, or in which the tension is associated with tender lymph nodes, indicates incision and should be opened under a local anesthetic. A boil that has been adequately incised at the right time will require no more than a piece of rubber dam for a drain, aided by 2 per cent salicylic acid ointment to keep the incision open. Areas surrounding any of these lesions should be shaved sufficiently to prevent adhesive plaster used in dressings adhering to any existing hair. Benzine should be used to float off such adhesive followed by alcohol and careful cleansing with hydrogen peroxide and green soap. Any irritation should be treated with calamine solution without phenol until the irritation has subsided. Lesions in specific regions call for special procedures in conjunction with the foregoing. The specific technic for caring for furuncles and carbuncles of the nose, upper lip, axilla and face is outlined. One of the most emphatic "don'ts" in surgery is don't squeeze; puncture these lesions with a needle or sharp instrument to prevent injuring the protective barrier that has formed around minute nasal furuncle infections. Physicians and nurses are conspicuously remiss in handling infected dressings with ungloved hands and without instruments. It is imperative when doing dressings of boils and carbuncles and infected cases always to use instruments to handle the dressings and sponges and sterile gloves when possible to avoid contaminating themselves, associates and patients. A small infection with three or four closely grouped openings can be treated as a boil unless it presents a picture of spreading induration with slight tenderness. Then it should be treated as a carbuncle. In diabetic patients any suppurative process tends to maintain a high blood sugar. This calls for a more complete and immediate eradication of the suppurative or necrotic lesion than in the nondiabetic. Operative procedures for other than the smallest lesions should be done in a hospital. It affords an assistant for retraction and exposure to remove necrotic tissue and control bleeding, as well as a surgical nurse and anesthetist. Before discharge the patient should be instructed how to care for any small follicular infection that might develop and to use all the prophylactic measures possible. Hydrogen peroxide should be used for its mechanical cleansing. The author has used a single application of gentian violet and methylene blue 5 per cent solution in 70 per cent alcohol, as advised by Kingsley Roberts for skin infection over limited areas with success in conjunction with the foregoing principles. He believes it is an excellent penetrating, nonirritating skin disinfectant with a prolonged action. Soap and water followed by ether are sufficient for preparing the skin. The use of vaccines in the presence of careless surgical cleanliness is of little value and should not be relied on.

to do a surgeon's work. However, in conjunction with careful clean surgery they are occasionally an aid in stubborn cases. The relationship of staphylococcus carriers to generalized staphylococcal infection is discussed.

Headache from Nasal Wall.—The source of a particular headache or pain of nasal cavity origin is described, involving the trigeminal nerve. Burnham advances a hypothesis for the explanation of this headache or pain: 1. The irritation within the nasal mucosa from the products of bacterial invasion produces a hypersensitive or susceptible state. 2. As a result, substances normally produced in the tissues from external stimuli, such as changes of atmosphere, drafts, and the like, cause excessive stimulation of the neurovascular mechanism and sensory nerves. The headache or pain that results is in the nature of a "referred pain" and involves one or more branches of the trigeminal. 3. The "tender spot" beneath the nasal bridge is believed to be due to pressure from congestion on the trunk of a hypersensitive nerve (a branch of the anterior ethmoid) in a bony foramen or canal, and this in turn may aggravate or produce the headache or pain. The hypothesis applies to the pain associated with sinusitis. A cotton applicator introduced into the nasal cavity will indicate, as a rule, a hypersensitive condition of the mucosa. If the cotton is moistened with a 3 per cent solution of ephedrine in saline solution and applied to the middle turbinate, spectacular relief may be experienced by the patient in a few minutes. He will say in a surprised tone that "the headache is gone." A further search was made for tender spots with the finding of an excessively tender spot just beneath the bridge of the nose.

When a cotton applicator soaked in ephedrine was passed along the bridge of the nose in the narrow channel formed at the junction of the septum and the lateral nasal wall, the patient experienced a sudden severe pain. In a few minutes, as a rule, great relief is experienced from the headache, and the "spot" becomes less tender. This "tender spot" is situated over the course of the lateral nasal nerve, a branch of the anterior ethmoid. Presumably this nerve, or a branch of it, leaves the bony canal at this point in these cases and is subject to pressure from the vascular coat in the periosteum about it. The ephedrine causes contraction of the overlying veins and presumably those in the neighboring canal, and in this manner the pressure on the nerve is relieved. The result is often amazing and of diagnostic significance.

Eighth Nerve High Tone Deafness and Nutrition.—Selfridge declares that the work of Peters of Oxford proves conclusively that some factor in the vitamin B complex is necessary for perfect biologic equilibrium. Thus the oxidative reduction system is necessary in order to prevent the accumulation of lactic acid in certain parts of the brain. The finding of a definite demyelination in both branches of the eighth nerve in a series of rats and chicks on a diet deficient in the different factors of the vitamin B complex B₁, B₂, and especially the filtrate factors B₆B₇ or K₁K₂ as shown in Covell's histopathologic studies, warrants the assertion that the lack of sufficient vitamin B in the human diet is probably the principal cause of the degeneration found in the eighth nerve. The clinical use of B₁ parentally, B₁B₂ absorbate, and particularly the rice bran B complex, appears to be the cause of the improved hearing noted in the audiograms of clinical cases. Large doses of carotene (30,000 units daily) over a period of months have caused no further change in hearing as demonstrated by the audiograms. Perhaps if the dosage of carotene or vitamin A was carried on over a longer period under the control of the photometer, further changes might be noted. The use of thyroid, except possibly in rare cases, does not influence the nerve changes. Its effect probably is to help in the general metabolic processes. The lowered basal rates in many instances are related to nutritional deficiencies. Cody's finding of a whitish edema in his animals on a vitamin B deficiency diet, and as seen in human beings with the pharyngoscope, appears to be somewhat conclusive as to vitamin B deficiency. No interpretation can be made regarding the finding of high tone deafness in the linear type of body build.

Cervical Rib and Scalenus Anticus Syndrome.—In order to emphasize some of the points in the differential diagnosis, the surgical indications and results of cervical ribs, Craig and Knepper report six cases. The clinical picture of cervical ribs and that of the scalenus anticus syndrome are similar, as are also the surgical indications and operation. The symptoms result from compression or irritation of the brachial plexus and compression of the subclavian artery. Compression may

be due to the presence of cervical rib, an abnormally low position of the shoulder, high fixation of the sternum and ribs, low origin of the brachial plexus or elevation of the first thoracic rib from spasm of the scalene muscles brought about by irritation of the brachial plexus. When cervical ribs cannot be demonstrated, resection of the scalenus anticus muscle is usually all that is necessary to relieve the symptoms. In the presence of a cervical rib without tendinous attachments and without obvious pressure from behind, resection of the scalenus anticus muscle is all that is necessary, but when there is evident pressure from the cervical rib or its tendinous attachment, resection of the rib and the attachment should be carried out. In carefully selected cases in which the symptoms point clearly to either cervical rib or the scalenus anticus syndrome, the surgical result is usually excellent.

Ganglions and Synovial Cysts.—With no sharp line of demarcation between them, Jensen classifies the cases into two general groups. Twenty-one cases from the records of the Knickerbocker and New York hospitals fall into the group of simple cystomas. Except for the presence of the cyst, they have few clinical symptoms to distinguish them. The age limit shows wide variation: The youngest in this series was 4 and the oldest 67 years of age, with the largest number appearing in the third decade. The duration of the cyst varied from six months to two years. The patients sought treatment because of the unsightly appearance, and a few because of fear of malignancy. In a second group, comprising twenty-three cases from the records of the New York Hospital, there were present, in addition to the cyst, signs of further involvement of the tissues as indicated by the frequency of pain and limitation of motion. With the exception of one case, the latter sign was present in all the cases of this group. The degree of limitation varied; at times it was so slight as not to be obvious to the patient and at other times it was rather pronounced. The clinical history in all was similar, as were the physical signs. A "doughy feel" or crepitus of "rice bodies" has been described as characteristic of a tuberculous process. "Rice bodies" can be present without evidence of tuberculosis. In this group no such clinical sign was noted. Yet a few presented an advanced tuberculous process when the tissue was examined; therefore it is important that the examiner should not wait for these two signs before a clinical diagnosis of tuberculosis is made and radical measures are instituted. The various theories on the origin of ganglionic and synovial cysts are presented, with a comparatively new one restated: namely, that they have their origin in embryologic arrests in the process of the development of the periarticular tissue and synovial membranes. When a cyst is present with pain and limitation of motion, however slight, early operation is indicated because the underlying pathologic condition is usually chronic inflammatory or tuberculous in character. Operation and complete excision of all involved tissue result in the highest percentage of cures. A certain percentage of failures occur even after the most careful dissection, but the number can be reduced by early and complete excision of all diseased tissue.

Vitamin C Deficiency and Wound Healing.—According to Lanman and Ingalls, guinea-pigs were partially depleted of their cevitamic acid depot and were subsequently maintained on approximately one fifth of the minimal protective daily dose of cevitamic acid. The healing of the operative incisions of these animals, both histologically and physiologically, was inferior to that of a group of control animals. A normal wound is believed to attain the greater part of its final strength within the first ten days after operation, but the partially scorbutic animals had greatly inferior tensile strength, when compared to their controls, ten, twenty and thirty days post-operatively. The abdominal wounds of the scorbutic group ruptured at a pressure averaging approximately one-third that required to rupture the wounds of the normal animals. The scar tissue in these wounds was distinctly abnormal, being livid and soft in consistency. Microscopic study of the wounds in the partially scorbutic group showed defective repair of the corium, and a poor production of collagen in the scar. A clinical case is cited in which the presence of asymptomatic scurvy is thought to have been a factor in the failure of an

operative wound to heal. There may exist in human beings a degree of vitamin C deficiency that cannot be recognized by methods ordinarily used in physical examination. It has been proved, histologically and chemically, that asymptomatic scurvy is far more common in infants and children than has been realized. Its existence in older patients, though not yet proved, undoubtedly occurs. When a low cevitamic acid depot in a patient is found or suspected, the giving of cevitamic acid, as an aid to wound healing, seems amply justified.

Dermatitis, Paralytic Ileus and Intestinal Perforation After Arsphenamine.—Dennie and Miller report two cases of arsphenamine dermatitis, in one of which death was due to adynamic paralytic ileus with perforation of the large intestine with resultant peritonitis. They believe that the perforation of the intestine was due primarily to involvement of the vessels of the intestinal wall. Hemorrhages in the lining of the stomach and intestine are not uncommon. It is believed that the neoarsphenamine or some of its side-products injured the blood vessels to such an extent that they were thrombosed, and localized necrosis of the intestinal wall resulted. In addition, there might have occurred a paradoxical therapeutic result of such intensity that the endothelium, in response to the physiologic stimulation, left the walls of the blood vessels so rapidly that they were either ruptured or closed with resultant localized necrosis. The latter view is based on the assumption that the endothelial lining of blood vessels is a part of the reticulo-endothelial system—a part of the defense mechanism. Both patients had an adynamic paralytic ileus. Whether the ileus preceded the perforation of the intestine is a debatable question.

Arsphenamine-Resistant Syphilis.—Netherton cites two instances of conjugal syphilis of the early type in each of which only the wife showed drug resistance. In one case the infection was resistant to the arsenicals and to bismuth and mercury compounds, while in the other the infection was resistant to the three most commonly used arsenicals. A resistance to both arsenic and the heavy metals tends to invalidate the theory of an arsphenamine-resistant strain of *Spirochaeta pallida*. In each case spirochetes were present in the cutaneous lesions several weeks after antisyphilitic therapy had been instituted. The observation of Moore and Robinson, Jessner and others that persons with arsenoresistant syphilis usually tolerate arsphenamine poorly and frequently exhibit psoriasiform lesions is well exemplified by the two cases reported. The drug resistance in only one of the marital partners cannot be explained on the basis of an arsphenamine-resistant strain of *Spirochaeta pallida* or as a result of a decrease in the spirocheticidal activity of the drug which was administered. The host must be incriminated. In one case the resistance of the infection to arsphenamine, bismuth and mercury disappeared after malarial therapy. This beneficial effect of fever therapy presumably arose from the decrease in vitality of the spirochetes by direct action of heat, the stimulation of the body

defense mechanism of the patients and an increase in metabolism incident to fever, which may have produced alterations within the host, thus facilitating the action of arsphenamine subsequently observed.

Treatment of Petrositis.—Beck and Guttman assert that not all cases of petrosal involvement require surgery. It is conceivable that the petrous tip may be but mildly involved in the pathologic process, and it has probably been the experience of most otologists that many of their patients with mastoiditis with pain in and about the eye have recovered without a petrous operation. Myerson states that about 80 per cent may recover with conservative management. While no hard and fast rule can be drawn, conservative management seems to be indicated only in those cases in which the pain is mild and decreasing in intensity, in which the temperature is normal or slightly elevated, in which the discharge has not ceased abruptly, and in which the roentgen observations show either a normal or slightly involved petrous tip. On the other hand, pain increasing in intensity, especially if it is nocturnal and interferes with sleep, an increasing temperature, a sudden cessation of the discharge, positive roentgen observations and signs of sepsis or meningeal irritation all point to an immediate evacuation of the petrous tip as a means of preventing further progression of the purulent process toward the cranial cavity with the possible production of a fatal complication. The danger lies not in the operation but in the delay, during which meningitis, brain abscess or cavernous thrombosis may supervene.

Reinfection in Experimental Poliomyelitis.—Flexner finds that monkeys which have recovered from an attack of experimental poliomyelitis are subject to reinfection by the nasal route. Second attacks of the disease result from inoculation with the specimen of virus used to produce the first attack and with specimens of different origin. Reinfection takes place in monkeys that have recovered from mild and from severe attacks and in convalescent animals that have been subjected to hyperimmunization. The quiescent period of two years proposed by Still to separate relapses from second attacks, judging from the monkey, is probably excessive. Until greater attention is given the reinfections of varying intensities in man, conclusions on this point must be wholly tentative.

Active Sensitization with Poison Ivy.—Straus has artificially sensitized rhesus monkeys to poison ivy. Such sensitized animals have been shown also to be specifically sensitive to poison oak. This not only demonstrates the common antigenic principle in the two substances but confirms the specific nature of the cutaneous reactions obtained. Sensitivity lasts at least eight months. For experiments in contact dermatitis the rhesus monkey presents advantages over other laboratory animals because it is more closely related to man and because, as judged by these experiments, his reactions closely simulate those observed previously in infants. Further investigations, which are impracticable in man, are made possible by the use of the rhesus monkey.

Passive Local Cutaneous Sensitization with Human Reaginic Serums.—Straus finds that locally the skins of rhesus monkeys can be sensitized passively with a majority of human reaginic serums of high titer. This property was heretofore considered peculiar to the human skin exclusively. The reaction that develops at the passively sensitized site consists almost entirely of edema and is not, as a rule, associated with erythema or pruritus. Many phenomena associated with passive local sensitization in man can be reproduced in monkeys. The specific nature of this local cutaneous sensitization with human reaginic serums has been clearly demonstrated.

Bacteriologic Study of Dysentery.—Haynes made bacteriologic studies of forty cases of dysentery. Eighty-four specimens, obtained by swabbing the mucosa during proctoscopic examination, were cultured and seventy-eight of them were examined microscopically for protozoa. Twenty-six stool specimens from these patients were cultured and two blood cultures made. The Flexner bacillus was obtained from thirteen cases, including two from which this organism was obtained in blood culture. It seems that the dysentery bacillus can enter the blood stream, but the frequency or time of its appearance there is not yet known. The Sonne dysentery bacillus was isolated from five cases; a bacillus obtained from a sixth case, which unfortunately was not completely studied, probably was also a Sonne bacillus. Sonne dysentery is probably endemic throughout this country, but because the disease is usually mild and because of the difficulty in recognizing the organism, cases are not reported frequently. It seems probable that adult carriers of this organism may be quite common and that some of the mild food infections may be caused by the Sonne bacillus. Unless a titer of well over 1:100 is obtained, the agglutination reaction is of doubtful value for diagnosis, as agglutinins may be present in lower titers in the blood for some time after the disease and negative agglutination tests do not exclude the disease.

Acute Surgical Conditions of Abdomen in Psychotic Patients.—Lewis states that psychotic patients should be observed closely for any abnormality in their behavior which may suggest an acute illness. Many of them do not make any complaints or give any subjective symptoms when suffering from an acute surgical condition of the abdomen, and it is by some abnormality in their behavior that the illness is first detected. Frequently these patients exhibit no abnormality in behavior until several days after the onset of the disability, and therefore the pathologic changes are quite extensive when the illness is detected. The clinical picture presented is often

not typical of any specific disease but only suggestive of an acute surgical condition of the abdomen. There should be no hesitancy in resorting to exploratory surgery rather than to wait for a positive diagnosis. Frequently, when the changes are sufficient to make a positive diagnosis, the disease is so far advanced that the prognosis for recovery with the proper surgical treatment is unfavorable.

Diabetes Mellitus.—Tuttle states that heredity appears as a factor in the incidence of diabetes mellitus. In the group studied, 33.3 per cent definitely showed hereditary origin; 35.7 per cent showed no indication of hereditary origin, while 31 per cent were unknown. Of the last group, many of the children were of foreign birth, who knew little about their antecedents, and it is therefore safe to assume that in many of these cases the question of heredity would be definite. It is now the accepted theory that hereditary diabetes follows the mendelian recessive pattern. Thus it would follow that for proper control diabetic children should be trained to marry into pure nondiabetic families. More advanced and recent studies of diabetes lead one to concur that diabetes is a disease of metabolism not only involving chemical abnormalities of the body fluids but also including disturbances of the glands of internal secretion, which affect the metabolic processes and disorders of nutrition. Since the metabolism of carbohydrates is in some way dependent on the function of the anterior lobe of the pituitary body and since in the menopause there is malfunction of the pituitary, it becomes more apparent that the menopause can contribute to the cause of diabetes mellitus, particularly in those who by inherited tendencies are potentially diabetic. The preponderance of females among the obese is another indicative factor. Disturbances due either to pregnancy or to gallbladder disease may be contributory causes of diabetes. There is apparently some important relation between glycosuria of long duration and the degree of arterial change as demonstrated by electrocardiographic observations, oscillographic readings and fundus examination. It would seem that the important factor lies in the prolonged and continued loss of sugar with its polyuria resulting in dehydration rather than in the amount of sugar lost at any one time. There is evidence that a diseased heart requires more carbohydrate than a normal heart. Hence lowering the blood sugar by rigid diet or insulin, or both, may aggravate the cardiac condition. The indiscriminate use of insulin, especially in the older diabetic patient with arteriosclerosis, is fraught with danger. The repeated hypoglycemic reactions caused by frequent insulin reactions in an apparently normal heart lead to physiologic imbalance and the

development of myocardial damage through changes in the intima of the arteries. It has been observed since the introduction of insulin that with more rigorous treatment of the diabetic patient the cardiac manifestations may become more severe instead of improved. High blood sugar values are often more benign in elderly diabetic patients with cardiovascular disease and it is best to undertreat them, especially if there is a history of coronary artery disturbance. Vascular diseases play a prominent part in the complications resulting from diabetes mellitus. Most of the patients in the present series having the disease for a number of years showed disturbances of the vascular system to a varied degree. Sixty-five patients, or 73.8 per cent, showed vascular disturbances. Joslin favors the theory that the usual increase in cholesterol in the diabetic patient's blood is responsible for the vascular change. Aschoff also believes that an increased amount of cholesterol in the blood is one of the prerequisites for arteriosclerosis.

Cholesterol Metabolism and Liver Disorders.—Epstein has found the study of the blood cholesterol partition a valuable adjunct to the clinical armamentarium in the differentiation of jaundice. The single determination will often mislead, since variations may occur depending on the time that elapses between the onset of the disease process and its study by the clinician. In a determination requiring so little blood, repeated studies are easily carried out. In obstructive jaundice a hypercholesterolemia is usually encountered, both of the free and of the ester fractions, which parallels the degree of hyperbilirubinemia. With relief of the obstruction and lessening of the jaundice, the cholesterol gradually returns to normal. This rise may not occur in long standing biliary stasis, superimposed infections of the biliary passages, cachexia and other complications. In jaundice occurring in acute hepatic degeneration, the blood cholesterol does not rise parallel to the bilirubin but usually remains at a normal or subnormal level. In severe cases, especially yellow atrophy, the blood cholesterol may be markedly depressed. This divergence between the degree of the blood cholesterol and bilirubin in hepatic diseases contrasts sharply with the parallelism between the hypercholesterolemia and hyperbilirubinemia in obstructive jaundice. The cholesterol esters are usually lowered in acute liver degeneration. The blood cholesterol partition remains normal in atrophic cirrhosis of the liver (Laënnec), except when jaundice occurs in the course of an intercurrent acute hepatic degeneration or terminal cholemia. In these instances the blood cholesterol partition behaves as in primary acute hepatic degeneration. In cholecystitis and cholelithiasis with no obstruction and no complicating infections of the biliary passages, the blood cholesterol figures are not significantly altered.

Relation of Spread of Infection to Fascial Planes in Neck.—Coller and Yglesias describe the three spaces (the space for the body of the mandible, the masticator space and the parotid space), lying between muscular fascial planes, that are limited by bony attachments above in the face and below to the thoracic cage. Infections in these are infrequent and are limited sharply to the neck. Between these spaces and the prevertebral muscular fascia lies a large viscerovascular system of fascia in which there are four definite fascial compartments and a vascular sheath. The lateral pharyngeal space is a receiving station for infections arising from fascial spaces in the face and pharynx, from which infection in turn may pass to all other compartments of the viscerovascular system. Two other compartments, the pretracheal and the retrovisceral, pass directly into the thorax. Infections passing along the sheath of the vessels will likewise pass directly to the thorax. The mediastinum may be very simply divided into compartments. Immediately behind the sternum is the space commonly called the anterior mediastinum; that is, a retrosternal space occupied by a few lymphatic glands, fat and areolar tissue. It is bounded posteriorly by the pleurae and the fascia connecting them. It is of surgical importance only in association with trauma and infection arising in the sternum. Posterior to this in its upper portion lie the thymus and the innominate veins with their fascial covering walling off the upper part of the retrosternal space from the neck. Behind this, between the pleura and the pericardium, lies the pleuro-pericardial space, which may be infected from the vascular sheath or from the pretracheal space. Posterior to this space are the ascending aorta and the arch of the aorta with their sheaths. Behind them lie the pretracheal space and just behind this the retrovisceral space, both of supreme importance because they are the major pathways for the entrance of infection to the thorax.

Pneumococcic Peritonitis.—Owing to the discrepancy of various features of pneumococcic peritonitis revealed in the literature, Cole studied the twenty-six cases that occurred in the St. Louis Children's Hospital during the last eighteen years, from which he deduces that the development of peritonitis secondary to infections such as those of the upper part of the respiratory tract is more common than any other mechanism in pathogenesis. He is of the opinion that the correct diagnosis can usually be made in differentiation from acute appendicitis, by noting such features as early development of fever, profuse vomiting, diffuse character of tenderness and pain and prevalence in girls. Diagnostic puncture of the abdomen is justifiable in children when diagnosis is uncertain and rarely fails to aid in the establishment of a correct diagnosis if the peritonitis is of pneumococcic origin. For many reasons immediate operation appears to be contraindicated. Although the present series is far too small to allow conclusions regarding this point, the results favor waiting until a localized abscess forms. If the child survives the acute stage of the disease, recovery is almost certain even though one or more localized abscesses form, provided, of course, such abscesses are properly drained. Pneumococcic peritonitis is a common complication of nephrosis. The mortality in these children was 54 per cent, as contrasted with 44 per cent in the previously healthy children.

Acetylsalicylic Acid Poisoning.—Williams and Panting consider the pathologic and biochemical basis underlying the clinical manifestations of profound toxemia in acetylsalicylic acid poisoning and discuss its theories. In their two cases with recovery after the ingestion of 2 and 3.8 Gm. of the drug respectively, the weight of evidence seems to be in favor of the intoxication being possibly a toxic action on the respiratory center but chiefly due to an acidosis. This is borne out by the rapid improvement in the clinical condition that accompanied the rise in the alkali reserve following the administration of sodium lactate solution intravenously by the slow drip method. Odin (1932) warns one to be careful in using salicylate in nephritic patients. In two of his cases albumin was present in the urine before treatment was commenced, and both patients developed symptoms of poisoning with so small a dose as 45 grains (3 Gm.) a day. All his patients had a moderate number of red blood cells in the urine, five had albuminuria and two had some casts. This, considered with the postmortem observation of acute nephritis, indicates that it is difficult for nephritic patients to excrete salicylic acid.

Aneurysm of Sinus of Valsalva Involving Coronary Orifice.—The inclusion of the coronary orifice in Schuster's case of aneurysm made it difficult at first to be certain whether the dilatation had originated in the coronary artery or in the sinus of Valsalva, and it was only after the remains of the artery had been dissected that the diagnosis was established. These aneurysms give notoriously complicated physical signs and they are rarely diagnosed during life. In the present case the early roentgenographic reports were misleading, as they persistently suggested neoplasm despite the clinical evidence in favor of aneurysm. There was evidently a difference of opinion about the nature and interpretation of the pulsation.

The sudden onset of marked pulsation and severe dyspnea with but little cyanosis were the most striking features. The aneurysm obstructed the tricuspid valve and it was considered that the apical systolic and diastolic murmurs belonged to that valve. The early harsh systolic murmur seemed to originate in the pulmonary artery and might have been due to pressure. The specimen was undoubtedly syphilitic, with a good deal of atheroma as well; in appearance it was just like an advanced saccular aneurysm of the arch of the aorta. Its size was exceptional (double fist), most of the recorded cases having been about the size of a walnut, while some of them were mere pouches.

 Anesthesia for Intracranial Operation: New Technic. P. Ayre.—p. 561.

Treatment of Nonmalignant Pyloric Stenosis.—Bennett explains the majority of the failures of medical treatment of pyloric stenosis by neglect to meet the requirements and habits of the individual patient. There is no other disease in which the personal factor is of more importance, and, if peptic ulcer is not treated more successfully in 1937 than it was in 1927, it is because many physicians and surgeons still continue to adopt a fixed system of treatment without realizing that, though it may be excellent, it must always require some measure of individual adjustment. An extreme illustration of this has been afforded by the transient popularity of the treatment of peptic ulcer by means of injections of histidine. Apart from ridiculous forms of treatment such as this, a proper proportion of successes cannot be secured unless each case is judged on its merits and the diet and medicine are arranged in each case so as to secure the measure of gastric rest necessary to bring about permanent healing and health. It is a mistake to assume that organic narrowing of the pyloric canal, even of high degree, must in all cases be treated surgically. Three cases are cited in which little or no vomiting occurred; this fact made it unnecessary to employ gastric lavage; the diet given in each case consisted of dextrose lemonade for a day or two, followed by diluted milky feeds, and proceeded to a semifluid diet for several weeks. The first and third patients were ultimately able to take a light diet differing little from that of other members of the household, but care was taken to avoid all foods calling for prolonged gastric digestion. The principal function of the stomach is to secure liquefaction of the food; recognition of this function enables one to classify the foods requiring prolonged gastric digestion with considerable exactitude; liquefaction does not connote solution, but the chyme is a thin fluid having the consistency of weak gruel. Success can seldom be achieved unless the patient with pyloric stenosis realizes that the diet he is given has been chosen in the not altogether optimistic hope of avoiding surgical operation.

Cutaneous Atrophic Striae.—Rosenthal presents four cases of cutaneous atrophic striae observed in young men suffering from pulmonary tuberculosis and mentions one case of macular atrophy. In none of the many cases of pleurisy with effusion that have come under his observation has linear atrophy been noted; and, further, in the cases reported, it was found impossible to correlate definitely the position of the patient in bed with either the distribution of the pulmonary lesion or the situation of the lineae. Posture in bed appears to be determined not only by the site of the disease in the lungs but also by subsidiary factors such as habit, inclination or immediate surroundings. The causes to be considered are maldevelopment (insufficiency of cutis, with deficiency of elasticity), rapid stretching (due to tumor, obesity, growth or pregnancy), endocrine dyscrasia (particularly pituitary abnormality) and toxic causes (tuberculosis, typhoid and cachectic states). From the embryology it is difficult to accept a deficiency of cutis as a primary factor, and probably the causation is multiple, the size and situation of the lineae being determined by external physical factors, together with purely local conditions in the skin that determine the lines of cleavage. Pulmonary tuberculosis,

being a disease that preeminently attacks young people at or about the growth period, involves treatment that favors the development of striae; i. e., prolonged rest. The tuberculous element plays little if any part in their causation.

General Practice: IX. Litigation. R. Forbes.—p. 317.

Treatment of Bedsore.—Love states that in the first stage of bedsore, or threatened bedsore, erythema of the skin, which disappears on pressure, is the earliest indication. At this stage moist dressings or ointments are contraindicated, and reliance is placed on prophylactic measures, combined with some preparation that will harden the skin if it is unduly soft. The application of 5 per cent silver nitrate in distilled water is useful or, alternatively, a solution of 30 grains (2 Gm.) of alum, 250 cc. of water and 250 cc. of alcohol, applied several times a day. Another efficacious preparation is equal parts of tincture of catechu and solution of lead subacetate. If the skin is harsh or dry, some protective covering may prevent the development of a threatened bedsore. If small areas are affected, several layers of flexible collodion painted over the surface may prevent the dry skin from cracking. In the second stage, or the inevitable bedsore, ulceration is imminent when redness and congestion appear and are unaffected by pressure. The best form of local treatment is the tannic acid spray utilized as for burns. A freshly prepared 5 per cent solution in distilled water is sprayed on at hourly intervals, and the affected surface is dried by an electric drier or by exposure to dry heat from electric lights. A tough and adherent coagulum forms after about twenty applications. Healing usually takes place in an uninterrupted and satisfactory manner. Occasionally pus collects under the coagulum; then the coagulum is either partly snipped away or removed entirely after softening by the application of gauze soaked in petrolatum. In uncomplicated cases the coagulum remains until healing is well advanced, when it is trimmed until the final portion detaches itself. Ulceration, or the final stage of bedsore, may spread in an alarming manner, and toxic absorption adds to the other burdens of the patient. Treatment may require almost daily variation according to the progress of the ulcer. Ointment and other greasy or oily preparations are unsuitable. In early cases of bedsore, treatment by elastoplast is always worth while. The plaster is applied so as to cover the ulcer and the surrounding skin. The plaster should not be stretched before it is applied, and it is left in position until it is loosened by the discharge. The loose plaster is removed, the ulcer is cleansed with sterile gauze and new plaster is applied. This process is repeated as often as necessary. Granulations are unimpaired by frequent dressings, and possibly the retained discharge possesses a proteolytic power that liquefies dead tissue. This treatment of bedsore resembles Winnett Orr's method in dealing with acute osteomyelitis. Only extending bedsore, when protection by plaster has failed, require moist applications. When the stage of healing is reached and the discharge becomes serous, the application of 10 per cent ichthammol in glycerin usually expedites healing. Red lotion or equal parts of zinc oxide and resin ointment encourage the growth of epithelium.

*Treatment of Furuncles and Carbuncles: Carbuncle in Hypoglycemia. L. Diamant-Berger.—p. 190.

Treatment of Furuncles and Carbuncles.—Many believe, Diamant-Berger states, that carbuncles and furuncles thrive best in debilitated and fatigued persons and yet rarely is absolute rest prescribed. It is also frequently believed that the staphylococcus likes sugar and that a diabetic patient constitutes a favorable medium for its development. As evidence against these well rooted ideas the author cites the history of a hypoglycemic patient with a large carbuncle on the neck, whose high temperature and general debility began to improve soon after the rectal administration of dextrose. The carbuncle itself, however, was not affected until after the patient had received strong doses of staphylococcus toxoid. The author believes that carbuncles and furuncles are never just local lesions but that septicemia should always be suspected. Perinephric phlegmons and osteomyelitis often follow. Thus cauterization of an immature furuncle is useless, even dangerous. Subcutaneous vaccination is the only useful treatment.

Initial Phase of Tuberculous Infection in Infancy. M. Lamy.—p. 94.

Treatment of Toxic Choleraform Syndrome of Infant.—Debré and his associates studied the hydrating effects of parenteral treatment. They found the Schick-Karelitz method of continuous intravenous injection with either Ringer's or isotonic salt solution to which a 5 per cent solution of dextrose has been added the most favorable. From 70 to 150 Gm. is injected, depending on the infant's weight, which gives the patient from about 12 to 25 drops a minute. No nourishment is given for from twenty-four to forty-eight hours and his lips are kept moist with a wet cloth. After that he may receive 20 Gm. of mother's milk, ass's milk or buttermilk. If no complications arise, this dose may be increased to from 60 to 80 Gm. every two and a half hours while the quantity of the injected salt solution is diminished. The median basilic vein, well recognizable in dehydrated infants, is used. The infant must be watched day and night. The number of drops injected must be recorded every hour. The immediate results of the injection are cessation of vomiting, natural sleep and replacement of dyspnea by rhythmic respirations. In about three days a rapid improvement of all symptoms is noticed, the alimentary equilibrium is established and the infant gains weight. The treatment may therefore be considered as directed not against the toxic infection but against the dehydration of the patient. In a few cases it happens that even after dehydration has been checked the toxic infection continues and the patient dies. If the temperature and vomiting persist and the face remains lifeless after the third day, there is little to be expected, especially in conditions of advanced cachexia.

Radiophysiologie et Radiothérapie, Paris

3: 281-470 (March) 1937

Surgical Treatment of Adenopathies of Cancer of Tongue. A. Tailhefer.—p. 419.

Effect on Ovary of Irradiation of Hypophysis.—Lacassagne destroys the hypophysis of the rabbit by introducing radium into the gland. The animal is immobilized and a trepanation of 5 mm. in width is made right between the two

orbital prominences of the skull. Through the opening he introduces a hollow needle containing radium which, penetrating the meninges, passes between the frontal lobes and reaches the base of the skull, where it enters the sella turcica from above, perforating the hypophysis. The needle is left there and the opening in the skull is closed. No anesthesia is needed, since the animals are not perturbed: they accept the male immediately after and become pregnant in from two to eight days. In most cases all sexual activity ceases after eight days following the treatment, and about one month later a distinct atrophy of the nipples and vulva is noted. In the killed animal there are marked cytolytic changes of the ovaries, which gradually atrophy to about a third of their original weight and size. Destruction of only the anterior portion of the hypophysis is accompanied by no changes of the sexual apparatus. The animals stand fractional roentgen treatments well (two of from thirty to seventy-seven minutes per week). From three to five months later the animals were killed and no changes were found in the genital organs of the male or female rabbits. Intense irradiation over large fields bring about general dysfunction.

Blood Transfusions in Pulmonary Tuberculosis.—Pierre-Bourgeois and his associates observe that medical literature contains little information about blood transfusions in pulmonary tuberculosis. The few authors who have nothing but praise for this form of treatment are forcefully contradicted by others. The authors obtained improvement in seven out of ten cases of hemoptysis by injecting small quantities in doses ranging from 50 to 150 cc. and never went beyond 300 cc., even in serious cases. The results obtained are superior to subcutaneous injections of oxygen. There were an improved coagulation and lessened hemorrhages, and a distinct increase in erythrocytes, lymphocytes, monocytes and eosinophils and in the percentage of hemoglobin. The polymorphonuclears were decreased. Transfusion is contraindicated in cachectic patients, patients with oscillating temperatures and those in whom the extent of their lesions renders their case hopeless. The improvements are not always stable. The favorable effect after the first transfusion may not continue after the successive transfusions. Besides these somatic effects there is also always a good psychotherapeutic effect.

Ascoli's Treatment in Malaria. M. Ascoli, A. Missiroli, A. Bonfigli, A. Casu, U. Diliberto, N. Musumeci, P. Riolo, Rocca and Terenzio.—p. 659.

*Treatment of Malarial Splenomegaly. F. Canova.—p. 670.

Intestinal Occlusion from Appendicitis. F. Sciacca.—p. 672.

Treatment of Malarial Splenomegaly.—According to Canova, administration of intravenous injections of progressive doses of from 0.01 to 0.1 mm. of epinephrine up to twenty-five injections (Ascoli's treatment) controls malaria and chronic malarial splenomegaly. The effects of epinephrine are similar to those of blood transfusion. Epinephrine has a tonic action on the heart. When the treatment is given in association with administration of quinine in acute malaria the depressive action of quinine on circulation is prevented. The repeated splenic contractions from epinephrine results in complete elimination of the parasites from the spleen, with consequent diminution of the danger of recurrence of the infestation and improvement of the patient's general condition.

Syphilis and Tuberculosis of Breast: Case. M. Bortolozzi.—p. 156.

*Glossitis from Vincent's Fusospirillary Symbiosis. A. M. Cicchitto.—p. 159.

New Type of Acute Adenolymphopathy.—Pirera describes a new epidemic disease which has been recently observed in Naples and in the country. The disease has a favorable prognosis and a brief evolution and is contagious. The incubation period lasts a week. The parotid and salivary glands become enlarged and painful at the onset. Fever, after chills, begins three days after the appearance of the glandular inflammation. Except for the parotid and especially the salivary glands, no other glands are involved in the process. The axillary glands are slightly painful but never enlarged. The spleen is slightly painful and enlarged. There is intense headache, lack of appetite and pallor all through the disease from the beginning of the incubation period. The fever and glandular symptoms abate and completely disappear in a week. Complete recovery is prompt. Urine is normal all through the disease. There are frequent and slight pharyngeal and conjunctival hyperemias. According to the author, the disease is caused by a lymphotropic virus which is like that of epidemic parotitis and the Filatov and Pfeiffer types of glandular fever. The disease slightly resembles epidemic parotitis and glandular fever, but it has some different symptoms, especially the selective localization at the salivary glands and the benign evolution without any complications. The author suggests calling the disease benign acute salivary lympho-adenitis.

Glossitis from Vincent's Fusospirillary Symbiosis.—Cicchitto has studied ulcerative glossitis caused by Vincent's organisms in natives in tropical countries. The mouth, pharynx and tongue are normal, except for the presence of a small painful pustule at the tip of the tongue, which in a few days goes through processes of necrosis and ulceration. The exudates and fragments of tissues from the ulcer show the presence of Vincent's fusospirillary symbiosis. There are no fever and general symptoms. Cervical and submaxillary adenopathies are present. The disease is unrelated to syphilis, avitaminosis, infections and exanthems. The treatment consists essentially in administering intravenous injections of arspenamine combined with local treatment of daily applications of arspenamine, methylene blue or of the following preparation: Castellani's fucin 100 Gm., resorcinol 1 Gm. and acetone and boric acid 4 Gm. each. Two cases are reported.

Costa Reaction.—Martini and Litter performed the Costa procaine hydrochloride-formaldehyde reaction on the blood serum of 119 persons. They used Rubenstein's technic with the following modifications: 1. The venous blood was taken from persons with a fasting stomach. 2. The concentration of sodium citrate in the blood was in the proportion of 0.5 per cent. 3. The time for reading the results varied from three to fifteen minutes when 0.1 cc. (2 drops) of blood was used in the reaction and from one to eight minutes when 0.15 cc. (3 drops) of the blood was used. Lack of flocculation after this time indicated negative results of the test. The authors conclude that the reaction gives always negative results in normal persons and positive results in infections, cancer and toxic conditions, such as genuine uremia. Gastric cancer and gastric ulcers can be differentiated from the results of the test, which has no practical application in diseases of the circulatory system. In certain cases the intensity of the results of the

reaction follow the evolution of the disease. The results of the test become negative a few days before death occurs and change no more to positive results. The results of the Costa test parallel those of the sedimentation speed of the erythrocytes. Costa's is a reaction of flocculation of the proteins in the blood serum. It depends on disturbances of the ratio of the albumins, globulins and fibrinogen in the blood plasma. The technic of the test is simple and the results are quickly obtained. The test is of clinical value and may be substituted for the test of the sedimentation speed of the erythrocytes.

Value of Sedimentation of Erythrocytes in Tuberculosis.—Castoldi says that the test is nonspecific in tuberculosis. However, when it is taken in association with the results of the clinical examination and of other laboratory tests, it is of diagnostic value in tuberculosis. It is also of prognostic value. The sedimentation of the erythrocytes is increased in grave forms of tuberculosis. The graver the type or evolutionary phase of the disease, the more increased the sedimentation of the erythrocytes. The test can be considered an index as to the improvement of patients, showing the efficacy of a treatment administered in given cases. A brief report of sixty-five cases, showing the relation between the sedimentation of the erythrocytes and the evolution of the disease in patients suffering from tuberculosis of different types, is given by the author.

Primary Muscle Tuberculosis.—According to Kushizaki and Saito, primary muscle tuberculosis belongs to the rarest lesions, the total number of cases thus far recorded not exceeding 100. The authors observed two patients recently operated on at the Kyusu University at Fukuoka. A review of the literature shows that the lesion was observed, in order of frequency, in the muscles of the forearm, the leg and the thigh, most frequently as a solitary lesion. One of the authors' patients presented a solitary lesion of the right pectoralis major muscle, while the second presented symmetrical lesions of all four extremities. The lesion is seen most frequently in young men. One of the authors' patients was a man aged 24 and the other a woman aged 34. In a number of cases, trauma or bodily overexertion seemed to play an etiologic part. The state of the primary tuberculous lesion does not seem to have any relationship to the genesis of the tuberculous process in the muscle tissue. Clinical and roentgenologic studies did not reveal any tuberculous lesion in their first case, while in the second the lesion present was that of roentgenologically demonstrated calcified tuberculous glands of the hilus. Muscle tuberculosis may present a nodular form, an abscess or a fungating sclerosing myositis. The abscess is the more frequent type, whereas the fungating form is the rarest. The lesion may run a latent course for months, manifesting itself as a movable, tender, subcutaneous tumor the size of a walnut. Its surface is smooth, the consistency not pronounced and the overlying skin normal. Clinical diagnosis is difficult, and histologic or bacteriologic confirmation is necessary. Neoplasms, parasites and chronic specific infections must be considered in the dif-

ferential diagnosis. Bier's hyperemia, tuberculin, puncture, followed by injection of 10 per cent iodoform in glycerin, and roentgen irradiation have been used in the treatment of the lesion. The authors believe that radical excision is indicated if one is to obtain an ideal result. General treatment of the patient is always indicated. Both of the authors' patients were cured by excision and roentgen irradiation.

Problem of Isolated High Sugar Content of Skin or Cutaneous Diabetes, Respectively. E. Urbach, F. Depisch and Grete Sicher.—p. 452.

Pathologic Elimination of Vitamin A in Urine.—Schneider and Weigand state that they investigated the elimination of vitamin A in 180 cases. The tests were made without and with the vitamin A tolerance test. It was found that the normal organism does not eliminate vitamin A in the urine even after a tolerance test with large doses. However, a large percentage of patients with cancer as well as of those with tuberculosis or with general infections did eliminate vitamin A in the urine. The authors regard impairment of the liver or a change in the renal permeability as the cause of this elimination. Depending on the quantity and the duration of the elimination, a hypovitaminosis may result from the loss of vitamin A.

Pregnancy and Hypovitaminoses of Intestinal Origin.—Gaetgens points out that it has been proved by others that the vitamin C requirements of the pregnant organism are increased. The fetus takes its requirements of cevitamic acid from the maternal organism, which in turn extracts them from the food. If the food does not supply adequate amounts, the maternal organism will show signs of vitamin C deficiency. If the development of hypovitaminotic conditions is to be avoided during pregnancy, it is necessary to exclude all exogenous and endogenous factors that are likely to increase further the already great cevitamic acid requirements. A deficiency of cevitamic acid in the food is an exogenous factor and all those conditions which prevent the proper utilization of the vitamin are endogenous factors. The author gives especial attention to the latter, particularly to disturbances in the gastrointestinal function. He reports the clinical history of a pregnant woman, aged 31, who developed ulcerous colitis and a severe deficiency of vitamin C. He emphasizes that whenever gastro-intestinal disturbances develop in the course of pregnancy it is necessary to supply the maternal organism with large quantities of vitamins by parenteral administration.

Development of Agranulocytosis in Treatment of Neurosyphilis. H. Sprockhoff and H. C. Buhrmester.—p. 408.

Treatment of Diabetic Coma During Childhood.—Priesel says that it should be remembered that diabetic coma is an intoxication of the organism with the excessively produced ketone bodies, but also that some of the clinical manifestations are the result of dehydration, in that the tissue cells have lost their capacity of binding water. In accordance with this, the following factors are essential in the treatment: 1. Insulin must be administered in order to aid the insular organ, which has suddenly become completely insufficient. 2. Fluids must be administered so as to combat the exsiccation. This also improves the circulatory weakness. The administra-

tion of insulin must begin at once and must be continued at intervals of one, two or three hours until a complete change is observable in the metabolic condition. The total dose depends on the severity of the coma. In order to avoid hypoglycemic complications, it is advisable to make blood sugar tests in the course of the treatment.

Specific Protein Allergy as Cause of Gout and Rheumatism.—Gudzent cites clinical observations which proved to him that the acute attack of gout is not the result of acute deposits of uric acid but rather an allergic reaction to a gout toxin in the ingested foods or drinks. He also observed patients with chronic articular rheumatism who stated spontaneously that they always felt worse after ingesting fish, eggs or milk. With protein substances of various origins he was able to produce in animals that had been sensitized to the particular foreign protein a disorder resembling human rheumatism. He found that thorough anamneses reveal that rheumatism or gout occurs almost exclusively in persons among whose blood relatives allergic disorders are found, such as bronchial asthma, hay fever, urticaria, eczema, migraine and lithiasis. Tests with solutions of proteins from meats, cereals, fish, vegetables, milk and eggs and also from mold and yeast fungi revealed that nearly all patients with rheumatism and gout had a hypersensitivity to one or several protein substances. About 35 per cent were sensitive to animal proteins, 55 per cent to vegetable proteins and 10 per cent to the proteins of mold and yeast fungi. Persons who were free from allergy produced no reactions, but those from families with allergy nearly all had positive reactions. On the basis of these observations the author concludes that the various forms of rheumatism are a hyperergic reaction elicited by a hereditary or acquired hypersensitivity to a foreign protein. The treatment should consist in elimination of the offending protein and in desensitization with the specific protein allergen.

Resistance to Inflammatory Disorders in Tuberculosis.

—Roloff points out that, although tuberculosis may concur with almost any disorder, it has been observed that intercurrent inflammatory disturbances are rare in active tuberculosis. To be sure, tuberculous patients who are in a sanatorium are protected against many external influences that might cause intercurrent disorders, but this factor was taken into consideration, and observations were made also on tuberculous patients who were only under ambulatory observation. Appendicitis, cholecystitis and nontuberculous nephritides are hardly ever observed in patients with open tuberculosis. Nontuberculous pneumonias have been reported in tuberculosis, but many of the reports are doubtful and it is generally conceded that the concurrence of pulmonary tuberculosis and lobar pneumonia is rare. The incidence and significance of true influenza in tuberculous patients is still a matter of dispute. It has been stated that inactive tuberculous foci were reactivated by influenza, but the author thinks that the action of influenza on tuberculosis, particularly the active forms, has been overestimated. He thinks that the many types of colds that occur in tuberculous patients are frequently tuberculous exacerbations that have been interpreted as bronchitis or influenza. He further states that pulmonary abscesses have only rarely been described in florid tuberculosis and, although the slow, tuberculous otitis media is well known in tuberculous patients, the acute, nonspecific otitis media is rare. Epidemics of chickenpox, parotitis, German measles and measles and occasional cases of scarlet fever that occurred in the children's department never attacked children with open tuberculosis. To be sure, the departments were separated, but possibilities of transmission were nevertheless present. Although the author has no definite proof that typhoid and dysentery are likewise rare in patients with open tuberculosis, he believes that here

too is some protection. Syphilis and gonorrhea, however, seem to stand apart, for against these the patients with open tuberculosis seem to have no resistance. The author believes that the tuberculous process develops powers that prevent the taking or the further development of nontuberculous processes. The mechanisms of this resistance are not understood as yet, but the author hopes that further investigations may clarify this problem.

 Etiology of Hyperchromic Anemia and Funicular Myelosis. F. Nagl.—p. 781.

Action of Rectally Administered Gases.—Kaunitz and Leiner point out that carbon dioxide therapy has gained in importance since it was realized that it exerts favorable effects on the circulation. In a number of human subjects with various disorders and in dogs they investigated how much carbon dioxide or oxygen is absorbed in case of rectal administration. It was found that the oxygen intake through the intestine is slight and has hardly any therapeutic interest. The carbon dioxide and the oxygen contents of the blood were not noticeably increased after the rectal administration of the gases, which seems to suggest that the carbon dioxide, which is taken in through the intestine, is absorbed by the tissues. The hemodynamic changes that are noticeable after the rectal administration of carbon dioxide indicate a modification of the large and small circulation. There is an increase in the beat and minute volumes, a slackening of the precapillaries and a reduction in blood pressure, which is especially pronounced in some cases of hypertension. Moreover, there is improvement in the capillary function and a modification of the vasomotor mechanism which results in acceleration of the blood discharge into the right side of the heart. The increase in the reduced arterial saturation indicates an improvement in the membrane function of the pulmonary capillaries. Studies on the elimination of water, minerals, nitrogen, urea and lactic acid revealed in general a slight increase in the elimination of these substances; especially pronounced were the changes in two cases of nephritis.

Ferment Deviation: Diagnosis of Pancreatic Disturbances.—Like Katsch, Brinck and Gülzow apply the term ferment deviation ("fermententgleisung") to the increased appearance of pancreatic ferments in blood and urine. The deviation of the ferment takes place when the physiologic ferment-lymph or ferment-blood barriers are interrupted. This can be caused by closure of the pancreatic ducts, by changes in the pancreatic cells and by acute decomposition of ferment-producing parenchymal cells. The authors limited their investigations to the diastatic ferment in blood and urine. It was their aim to determine when and under what conditions the diastase content of blood and urine is increased. After pointing out that the diastase content of the blood is composed of cellular diastase and of excretory diastase and that approximately half of the normal blood diastase is derived from the pancreas, they state that they made their studies with Baltzer's modification of Ottenstein's method. They observed deviation of the ferment not only in pancreatic disorders but also in other disturbances. During the acute stage of pancreatic disorders, deviation of the ferment may be found, whereas during the chronic stage, particularly in cirrhotic processes, the passage of ferment into the blood may be reduced. The change in the blood diastase values may be the manifestation of different stages in the disease of the pancreas. In circulatory disorders, increased blood diastase values indicate venous stasis, edema and perhaps hemorrhages. Reduced values suggest stasis induration. In pernicious anemia and in some cases of leukemia, the blood diastase values are increased. The increase of diastase in pernicious anemia is probably the manifestation of edemas. If deviation of the ferment occurs in infectious diseases, it may

be the manifestation of serous pancreatitis or of a pancreatic hemorrhage. The reduced passage of ferments into the blood suggests a chronic cirrhotic inflammation or a ferment blockage resulting from a parenchymal impairment. Disturbances in the organs adjoining the pancreas are often accompanied by deviation of the ferment as the manifestation of a hyperemia, of a canalicular sialangitis or of penetrating processes. In diabetes mellitus the blood diastase is reduced. The authors conclude that, although the determination of the diastase content of the blood cannot be a substitute for a differentiated clinical diagnosis, it suggests the possibility of a pancreatic disorder whenever it differs from the normal content.

Treatment of Carcinoma of Female Urethra. J. Rivoir.—p. 714.

Eclampsia and Renal Decapsulation.—Ahrens reports the history of a woman who six weeks before her expected delivery suddenly developed convulsions. Venesection, the administration of narcotics, rupture of the bag of waters and metreuryasis were of no avail, for several hours later the patient was in eclamptic coma but delivery did not take place. A cesarean operation was considered inadvisable, because the many vaginal manipulations, cervical tears and other complications involved the danger of infection. Renal decapsulation was decided on. After this operation the convulsions ceased at once, but the patient still remained unconscious. Labor pains set in again and a living child was born. Gradually the mother's consciousness returned, but slight psychic disturbances recurred for a time. In the evaluating discussion the author points out that, if the case had been under his observation from the beginning, he would have resorted to a cesarean operation, but he admits that the renal intervention was not only less harmful but also more advantageous for the later functional and organic restoration of the kidney. He admits that it is not advisable to draw general conclusions from the favorable course of one case, but he thinks that in similar cases, particularly in severe early eclampsia when conservative measures fail, renal decapsulation would be preferable to a cesarean operation.

Wiener klinische Wochenschrift, Vienna

*Simple Internal Medicinal Treatment of Acute Coryza. F. Hutter.—p. 376.

Therapy of Thrombophlebitis and Thrombo-Embolism. C. Ewald.—p. 377.

Myxedema in Syringomyelia.—Dussik states that the concurrence of myxedema with syringomyelia, both of which are comparatively rare, has been reported only once before but that nervous disorders have been repeatedly observed in the ascendancy of patients with myxedema. He himself observed a patient in whom a classic myxedema developed many years after a syringomyelia had become manifest. It is noteworthy that the myxedematous changes developed at first in circumscribed areas that were most affected by the syringomyelia. In addition to the physical changes there also developed mental disturbances. The memory became impaired, there was drowsiness, the thinking process was slowed down, the same thoughts and actions recurred, and there were frequent agoraphobic manifestations. In discussing the connections between the myxedema and syringomyelia, the author suggests that a disturbance in the cervical sympathetic, which develops in the course of the syringomyelia, may have impaired the sympathetic innervation of the thyroid. In this connection it is pointed out that syringomyelia has been known to concur with exophthalmic goiter. On the other hand, it is possible that central sympa-

thetic factors might have played a part in the development of the myxedema. The author says that treatment with a thyroid preparation produced favorable results in the reported case, in that the myxedema symptoms disappeared. The symptoms of syringomyelia, however, remained unchanged.

Treatment of Acute Coryza.—Hutter reviews the studies on the common cold reported by H. S. Diehl in THE JOURNAL, Dec. 23, 1933, pointing out that in trying various opiates Diehl found that the results were most favorable when a combination of codeine-papaverine was used. The author followed Diehl's suggestion in the treatment of cases of acute coryza, which he regards as a definite disease entity. He gave five times daily, for two days, a dose of codeine-papaverine and observed that, when the medication was begun sufficiently early, the effect was often noticeable after a few doses. He emphasizes that he employed the treatment only in cases of acute coryza, that is, during the "running stage," for Diehl had observed that during the subacute phase with its mucopurulent discharge the codeine-papaverine treatment is no longer effective, because secondary infection has already set in. The author also excluded cases of allergic rhinitis from the codeine-papaverine treatment and, by thus carefully selecting his cases for the codeine-papaverine treatment, he found it effective in all cases.

*Artificial Pneumothorax in Bilateral Pulmonary Tuberculosis. B. Z. Bunina, A. O. Gurevich, M. P. Rosenoer and A. D. Kulikov.—p. 78.

Laboratory Diagnosis of Tuberculosis.—Ozol's method of microscopic examination of the sputum, urine, and pleural exudate consisting of concentrating the material to be examined by dissolving it in antiformin, centrifugating the dissolved matter and subjecting it to the author's thick smear method of staining published in 1934 proved to be as reliable as the biologic test. The latter was positive in only one of 125 cases that were negative with the bacterioscopic antiformin thick-smear method. In two cases the microscopic examination of a thick smear antiformin preparation was more sensitive than the biologic test. In some of the author's cases of experimental tuberculosis in guinea-pigs, the diagnosis could be established in the absence of loss of weight, of a positive Mantoux reaction, of gross pathologic lesions or tubercle bacilli in the organs, on histologic examination of the tissues only.

Artificial Pneumothorax in Pulmonary Tuberculosis.—Bunina and her associates report observations on 219 patients with an active bilateral pulmonary tuberculosis treated either by a unilateral or by a bilateral artificial pneumothorax and observed for a period of six years. In sixty of the cases, unilateral pneumothorax was induced. The authors reject the theory of bronchogenic aspiration in the genesis of the development of the tuberculous lesions in the lung opposite that on which collapse therapy was practiced. Study of serial roentgenograms convinced them that the new foci in the opposite lung develop on the basis of preexisting lesions. They found that 38 per cent of their patients with infiltrating lesions were rendered bacillus free as the result of treatment with unilateral artificial pneumothorax, and the same effect was noted in 32 per cent of the cases in which there were disseminated foci. Sixteen of the sixty patients treated by unilateral pneumothorax developed a pneumopleuritis. Twelve of these were cases presenting caseating lesions. The authors conclude that recent infiltrating lesions with a more or less extensive involvement of the opposite lung without, however, clinically or roentgenologically demonstrable destructive lesion are best treated by a unilateral pneumothorax. Induction of artificial pneumothorax on the opposite side is indicated when the lesions there

begin to show signs of breaking down. The collapse therapy should not be postponed long. Simultaneous bilateral induction of artificial pneumothorax is indicated for cases exhibiting a recent infiltrating bilateral process with a tendency to break down or with disseminated foci and cavities. In cases in which there are recent bilateral lesions and marked predominance in one lung, one may commence with a unilateral pneumothorax. Bilateral pneumothorax therapy may be practiced in cases of bilateral caseating lobular pneumonia, but its effect is only palliative.

Influence of Histamine on Renal Function.—Bjerling presents an account of investigations on the influence of histamine on blood pressure and on the urea and creatinine clearances. The clearance of the two substances was determined in two periods, each of twenty or thirty minutes, prior to the histamine injection, and in the same period the blood pressure was measured regularly. After the histamine injection (1 mg. subcutaneously) the clearance was determined in periods of varying length. The blood pressure was measured every minute or every second minute. The patients were examined in the morning while they were fasting and in bed. There were seven in all, three of them with essential hypertension. The author observed that after the injection of 1 mg. of histamine the systolic and diastolic blood pressure falls. The systolic pressure decreases more in patients with essential hypertension than in those with normal blood pressure. Both creatinine and urea clearances decrease simultaneously with the blood pressure. However, there is no absolute proportion between the reduction in blood pressure and the decrease in clearance. Therefore the author is inclined to ascribe the latter to local circulatory changes in the kidneys. The concentration indexes for creatinine and urea rise simultaneously with the falling clearances, which indicates that both glomeruli and the vessels around the tubules are influenced by histamine. A comparison of the creatinine and urea clearances shows that the latter changes most. In one case, in which there was an especially great reduction in blood pressure, albuminuria occurred without any other demonstrable pathologic components in the urine. The total excretion of protein follows the fluctuations in the filtration. The total protein content of the blood does not change after histamine injection.

Primary Sarcoma of Small Intestine Diagnosed and Operated on as Uterine Myoma: Case. M. Renvall.—p. 119.

Roentgenologic Measurement of True Conjugate Diameter.—Madsen describes his experiences with a roentgenologic method of measuring the true conjugate diameter of the pelvis, which was first described by Weitzner in 1935. The projection is made while the patient is in the lateral position. Before the exposure is made, a metal ruler is attached to the patient's back with adhesive tape so that it passes over the spinous processes of the lumbar spine and sacrum. The lower end of the ruler lies in the cleft between the buttocks.

The central ray is directed against the posterior rim of the acetabulum. The accurate placement of the patient, the exact attachment of the metal ruler and the exact projection of the central ray are important for the correctness of the results. After explaining and illustrating the computation by means of a diagram, the author describes his experiences with the method in several women with narrow pelvis. The results are reliable and, since the method is comparatively simple, the author recommends it for clinical application.

Rational Principle for Leading Off Current in Registration of Precordial Leads in Clinical Electrocardiography. K. H. Larsen and E. Warburg.—p. 276.

Tuberculosis in Children.—With says that graduated intracutaneous tests were made in 116 tuberculous children with doses of from 0.000001 to 1 mg. tuberculin and that the proportion between the redness and the infiltration of the reaction was studied. The sensitivity was highest in primary tuberculosis, somewhat lower in pleuritis paratuberculosis, still lower in healed primary tuberculosis, and lowest in meningitis and miliary tuberculosis. The graduated intracutaneous test is therefore considered a valuable diagnostic aid in everyday clinical work in a children's department.

Application of Festal as Agent for Increase of Weight. I. Freuchen.—p. 282.
*Chronic Lead Poisoning: Case. A. Nyfeldt.—p. 283.

Hemorrhagic Diatheses.—Although he emphasizes that other factors may also play a part, the causes of hemorrhagic diathesis outlined by Holten according to the main pathogenic factor are (1) disturbances in coagulation, (2) changes in the blood vessels and (3) in some cases rarer disorders. The disturbances in coagulation depend (1) on changes in the blood platelets (a) of quantitative kind, due to impairment of the bone marrow function, as seen in essential thrombopenia, symptomatic thrombopenia (in aplastic anemia, leukemia, tumor, chronic benzene intoxication, acute febrile disturbances), and to disorders of the spleen in Banti's and in Gaucher's disease, and (b) of qualitative kind, in hemophilia, hereditary thrombasthenia and constitutional thrombopathy, and (2) on fibrinogen deficiency, seen in grave hepatic disorders. The changes in the blood vessels appear in anaphylactic purpura (purpura simplex, Henoch's purpura, Schönlein's purpura, allergic purpura), purpura fulminans, simple symptomatic purpura (in typhoid, endocarditis lenta, influenza, nephritis, meningococcal infection), in intoxication, C avitaminosis (scurvy, infantile scurvy) and in hereditary hemorrhagic telangiectasis. In the author's opinion essential thrombopenia is less rare than formerly supposed and he reports two of the eight cases observed by him in five years. There are three main methods of treatment: transfusion, the procedure in acute attacks, splenectomy, contra-indicated in acute cases, and roentgen treatment. Two cases of Henoch's disease are reported, also one of probable Banti's disease, not diagnosed until three years after the onset of recurrent gastric hemorrhages, in which blood transfusion made splenectomy possible, with improvement continuing three and a half years after operation.

Chronic Lead Poisoning.—Nyfeldt's patient is an employee of the criminal identification bureau of the police department whose daily occupation for twenty-six years has been the examination of articles for finger prints. He has dusted each article with large amounts of finely pulverized white lead, then brushed the powder away, bending over the article to detect possible prints, and thus inhaled considerable quantities of white lead. The first symptoms of lead colic and lead neuritis appeared twenty years ago; recently signs of lead arthralgia set in. The diagnosis was confirmed by the demonstration of 5 per cent basophil punctated erythrocytes.

INDICATIONS FOR THE OPERATIONS OF CARDIOLYSIS, PERICARDIOTOMY AND PERICARDIECTOMY

MOSES BEHREND, M.D.
AND
RUSSELL S. BOLES, M.D.
PHILADELPHIA

Our object in this presentation is to focus attention on the subject of pericarditis and to develop greater familiarity with certain operations performed on and around the heart. That there is a definite indication for these procedures is attested by the report of many cases in the literature. It is a matter of regret that surgery involving the heart is usually deferred so long that operation can scarcely be expected to afford any relief.

While pericarditis is not a common disease, it is unfortunate that it so frequently is overlooked. Post-mortem records have shown in the experience of one of us, while an intern in the Philadelphia General Hospital in 1900, that pericarditis was undiagnosed more often than any other disease. In the past ten years in the Philadelphia General Hospital, out of 19,500 postmortems, 146 cases of pericarditis were found, of which only 4 per cent had been diagnosed clinically. With the passing of the years, therefore, but little appreciable improvement has been shown in the diagnosis of pericarditis with or without effusion, despite the modern refinements in diagnosis derived from cardiograms, roentgenograms and the like. It has been noted that in many cases coming to autopsy the disease was so extensive that we feel certain that surgery could have helped save a life or at least prolonged it by easing the overburdened heart had it been recognized at its inception. It is surprising to note that surgical intervention was considered only in about three cases in ten years.

By way of introduction, brief reference will be made to the etiology and diagnosis of pericarditis in its acute and chronic stages.

Pericarditis is rarely, if ever, a primary process. While it more often develops as the result of rheumatic heart disease, chorea and cardiac infarction, it likewise is encountered as a complication of such common infectious diseases as pneumonia, scarlet fever, tuberculosis and septicemia. At times it may develop in cases of empyema or other local infections, especially of the mediastinum, as a result of direct extension. Occasionally it is observed in patients with gout and diabetes, and at times it is seen as a terminal event in

chronic nephritis and uremia. In some cases it is associated with chronic inflammation of the pleura and peritoneum, as in multiple serositis or Pick's disease.

Inflammation of the pericardium inevitably results in a fibrinous, serofibrinous or purulent exudate within the pericardial sac. In pneumonia and other acute severe infections the exudate is of a purulent type, while in the other conditions mentioned it is usually of a fibrinous or serofibrinous nature. In the absence of much effusion, the pericardial sac may be obliterated in part or completely as the result of adhesions, such a process usually being the result of rheumatic infection in childhood. Occasionally such obliteration may follow a tuberculous infection. Adhesions resulting from acute pericarditis may involve neighboring structures, especially the posterior mediastinum, pleurae and diaphragm. In such cases, signs of venous congestion are present and the condition is referred to as chronic mediastinopericarditis, or constrictive pericarditis.

It is unfortunate that a peculiar lack of symptoms frequently causes acute pericarditis to be overlooked. A suspicion of it may not be aroused because it is invariably a secondary process and such symptoms as it might create, such as precordial pain, dyspnea, palpitation and weakness, are apt to be masked by those of the primary disease. It is obvious under the circumstances that pericarditis will be recognized more frequently than it is only by one maintaining a constant vigilance and an awareness for its presence in all the more common conditions previously referred to in which it may be expected to occur.

Careful attention to physical signs affords the only reliable means of diagnosis. As stated before, there are no particularly significant symptoms characteristic of the disease in its early development. Even precordial pain, an acknowledged uncertain symptom, may be absent. In the fibrinous stage, a certainty that the disease exists may be felt only if the characteristic "to and fro" friction is audible. The friction may be heard anywhere over the precordium but particularly is to be found to the left of the sternum in the fourth and fifth interspaces. It characteristically appears to be close to the surface and corresponds closely to the systole and diastole of the heart. It is notoriously evanescent, lasting for several weeks or perhaps but a few hours, and may recur at most unexpected intervals. Once a friction rub has been heard, repeated careful search should be made for effusion. Roentgenologic examinations should be employed, if practical, as soon as the diagnosis of pericarditis has been suspected or established. By this means the earliest evidence of effusion may be secured. As the effusion accumulates, definite physical signs make their appearance and x-ray examination reveals a characteristic "water bottle" shape of the cardiac shadow. That an effusion is purulent may be suggested by the nature of the primary illness, such as

Read before the Medical Section, College of Physicians, Philadelphia, Nov. 23, 1936.
From the Medical and Surgical Departments of the Philadelphia General, Mount Sinai and Jewish hospitals.

pneumonia or empyema, an increased elevation of the temperature, and increasing leukocytosis. Chills, sweats and a rapidly developing anemia likewise indicate the presence of a purulent process and the necessity for paracentesis. If pus is shown to be present, immediate pericardiotomy is advisable.

In chronic adherent pericarditis, evidence of venous congestion is shown by increased venous pressure, engorgement of the cervical veins, enlargement of the liver and spleen, and ascites. When the pericardium is thickened and adherent and the sac is obliterated, the heart is smaller than normal. According to Willius,¹ calcification in the pericardium is found in about 10 per cent of cases of adherent pericarditis. In chronic mediastinopericarditis the heart is enlarged, presumably the result of the usually associated valvular disease rather than the handicap of surrounding adhesions. As the result of extrapericardial adhesions, such phenomena as systolic retraction in the region of the apex or posteriorly in the eleventh and twelfth interspaces, fixation of the apex beat or of the diaphragm and a pulsus paradoxus are usually to be observed. In any type of

Fig. 1 (case 4).—Case of tuberculous pericarditis. Typical water bottle shape of an effusion in the pericardial sac.

pericarditis, the assistance offered by x-ray examination may be found indispensable, especially in cases under surgical consideration.

While a serofibrinous effusion may occasionally require such a minor surgical procedure as paracentesis, it is the purulent effusion and the chronic adhesive type of pericarditis, requiring more radical surgery, that engages our attention in

this presentation. In the case of a purulent effusion, prompt recognition of the condition and adequate evacuation offer the only means of saving the patient's life. In chronic adherent pericarditis, a proper appreciation of the mechanical difficulties under which the heart is laboring and competent surgical correction of these difficulties may be expected to afford a more comfortable and useful existence for the patient than can otherwise be attained.

In a scholarly review of the literature on pericarditis, White² in 1935 quoted Galen (160 A. D.), Richard Lower (1669), Lancisi (1728), Morgagni (1760), Chevers (1842) and Wilks (1870) as all having recognized the existence of this disease, their description comparing favorably with those of modern authors. Of fifteen cases of chronic constrictive pericarditis, White in 1925 reported the first surgical cure in America in a girl 15 years of age. This patient has remained in excellent health for seven years. In these fifteen cases the symptoms were typical of adhesive pericarditis; that is, dyspnea, edema of the feet and ankles, edema of the face and upper part of the body, and ascites.

After the paper by Wilks the Germans became the leaders in the study of chronic constrictive pericarditis, and such men as Pick in 1896, Rehn in 1920, and Sauerbruch, Springer and Schmieden in 1923 and 1925 did important work in connection with this disease. The palm of distinction, however, belongs to Delorme,³ who as early as 1898 urged pericardial resection or decortication. Although Delorme was one of the first to advise excision of adhesions or decortication of the heart, he never practiced it himself.

Brauer⁴ in 1902 advised removal of the bony pericardium so that the heart would strike soft structures instead of a solid wall. This operation is of particular benefit in patients suffering from massive hypertrophy of the heart. In cases of adhesive pericarditis, however, the Brauer operation does little good unless it is supplemented by decortication. This opinion is confirmed by Bourne, Cutler, Beck,⁵ Poynton and Hirschfelder, Schmieden⁶ and Trout,⁷ who state that the operation of cardiolysis with decortication is generally beneficial.

Smith and Liggett⁸ in 1928 analyzed 107 cases of cardiolysis, which showed a mortality within three months of 20.6 per cent; 84 per cent of the patients had improved, 29 per cent becoming self supporting.

The Brauer operation owes its popularity to the fact that it is less hazardous. Beck stresses the fact that while the Brauer operation is less dangerous it attacks only the peripheral terminus of the cicatrix on the thoracic wall and that pericardiectomy, which was first performed by Hallopeau in 1910, is the more satisfactory operation. In Beck's estimation the Brauer operation is obsolete.

In 1934 Beck and Cushing⁹ discussed the subject of pericardial disease very fully. They described two different groups of symptoms, depending on whether the pressure is acute or chronic. Acute intrapericardial pressure is caused by hemorrhage, rupture of the heart or rapidly progressing suppurative infection. The clinical picture gives evidence of engorged veins, raised venous pressure, failure of arterial circulation, unconsciousness and faint heart signs. In the second type, chronic intrapericardial pressure results from the presence of effusion or adhesions such as follow a tuberculous infection. Here the clinical picture shows rise of high venous pressure, large liver and spleen, ascites and all the symptoms coincident with adhesive pericarditis. They report nine cases, six in which operation was done, with two deaths.

A year later, in 1935, Beck¹⁰ found that all intrapericardial lesions result in acute or chronic compression of the heart. Some of these cases give no symptoms and therefore cannot be recognized during life. The combination of extrapericardial and intrapericardial adhesions presents definite symptoms. In acute cardiac compression pericardiotomy should always be performed to determine the cause, whereas in chronic cardiac compression due to adhesions the Delorme decortication is advised.

Winkelbauer and Schur¹¹ advocate decortication of the left ventricle, especially when edema is present. They think it inadvisable to complete the operation in one stage. They perform, in the first stage, Brauer's operation for cardiolytic and object to the removal of calcified areas because the puncture of the left ventricle is impossible to close. In their report of eight cases, one patient was completely cured, three died, and there was improvement of the condition in the rest of the patients.

Griswold¹² in 1936 reported one case of pericardiectomy. Symptoms followed Beck's triad; namely, high venous blood pressure, ascites and a small quiet heart. He mentions the use of the roentgenkymogram as supplying irrefutable evidence of the reduced amplitude of cardiac pulsation and the throttling effect of the disease on the heart. After operation it showed the unmistakable benefits of pericardiectomy.

It will be noted that no attempt was made in the cases reported to control the rhythm of the heart at operation by the intrapericardial administration of drugs or to prevent an anticipated disturbance of rhythm by the preoperative administration of drugs, as has been referred to by Mautz.¹³ It would seem desirable, nevertheless, to consider such therapy in patients undergoing cardiac surgery.

REPORT OF CASES

CASE 1.—B. G., a white girl, aged 14 years, admitted to Mount Sinai Hospital June 1, 1925, was referred by Dr. H. B. Shmookler for operation. The primary diagnosis was aortic and mitral valvulitis and adherent pericarditis. The chief complaints were dyspnea, palpitation, weakness and pain. The patient had two previous admissions for heart disease. There was marked pulsation of the vessels in the neck; the apex beat was in the sixth interspace, 1 inch (2.5 cm.) outside the nipple line. Sounds were loud but not clear. There was no edema or cyanosis. A diagnosis of pericardial effusion was made, confirmed on the nineteenth by the cardiologist. X-ray films showed marked enlargement of the cardiac shadow, particularly on the left side. There was a strong suggestion of pericardial effusion.

The patient was readmitted to the hospital Oct. 29, 1926. On the second admission a history was obtained that she had been in the hospital four years before complaining of dyspnea and precordial distress of two years' duration. She had had scarlet fever and soon afterward typhoid.

Physical examination revealed a markedly enlarged heart with a double murmur at the apex and a systolic murmur at the base.

She had been admitted to the hospital a second time Sept. 10, 1923, with the same symptoms. The heart at this time was much larger. She was again discharged after successful treatment.

She was admitted a third time June 1, 1925, with the same complaints as previously. She had fever at this time and signs indicated pericarditis with effusion, which was confirmed by x-ray examination.

Blood cultures were sterile. The blood count showed mild polymorphonuclear leukocytosis. The Wassermann reaction and urinalysis were negative.

She was discharged again with the pericardial effusion entirely gone. On the fourth admission, Oct. 29, 1926, she was markedly dyspneic. The chest showed bulging on the left side around the precordium, with diffuse pulsations all over the precordium. The heart was greatly enlarged in all diameters. Murmurs were the same as on previous examinations. The blood pressure was 180 systolic, 130 diastolic. The heart occupied more than two thirds of the entire chest. After surgical consultation it was decided to resect several ribs to provide more room for the heart.

The diagnosis was adherent pericarditis; pancarditis with marked pericardial effusion; extensive hypertrophy with terminal dilatation, and terminal pneumonia.

At the operation, Nov. 9, 1926, the third, fourth and fifth ribs on the left side were resected and the wound was closed with clips. The pulse and respiration rate were increased. The wound healed well.

December 3 the patient was allowed out of bed in a chair. December 7 the temperature began to rise. The patient had an attack of nosebleed. The temperature ran an irregular course. From this time on the patient started to decline rapidly and eventually succumbed on December 27 from cardiac failure.

Summary.—A girl, aged 14 years, gave a history of scarlet fever and typhoid in childhood. She was practically hospitalized off and on for four years prior to operation. Scarlet fever was probably the cause of the pericardial infection. She had a huge heart. The third, fourth and fifth ribs were resected but the pericardium was not stripped. She was able to get out of bed twenty-four days after operation. Forty-seven days after operation she died of cardiac failure.

CASE 2.—J. J., a Negro boy, aged 12 years, admitted to the Jewish Hospital, Jan. 9, 1934, was referred by Dr. J. C. Doane for operation. The primary diagnosis was pericarditis and polyserositis. The chief complaint was dyspnea and pain over the precordium, cough and palpitation. The sickness dated from September 1933 following a "cold." He was told at that time that he had heart disease and an enlarged liver. Edema was present. He had had several aspirations of the chest and abdomen in the Philadelphia General Hospital, where he had stayed four months. He had had whooping cough, measles and chickenpox. He was a fairly well developed boy, though somewhat emaciated. The apex beat could not be felt; sounds were distant. The liver was palpable.

January 11 bilateral thoracentesis was done, yielding 14 ounces (420 cc.) from the right pleural cavity and 16 ounces from the left pleural cavity.

The blood chemistry was negative.

January 13, the Mantoux test was positive.

January 18, a pericardial tap was done and 15 cc. of turbid fluid was obtained. The cardiologist reported no definite evidence of myocardial disease, although there was some interference with function of the heart muscle.

X-ray examination confirmed the diagnosis of a huge heart with pericarditis and effusion.

Up to March 6 the pleural cavities were tapped almost daily. The diagnosis was rheumatic pancarditis, mitral stenosis and regurgitation, aortic regurgitation and pulmonic regurgitation.

March 6 the first stage of cardiolytic was performed. Portions of the third and fourth ribs were resected under local anesthesia.

March 21 the general condition seemed to be much better. There was little evidence of fluid in the pleural sacs and abdominal cavity.

April 3 the second stage of cardiolytic was done under local anesthesia. At this time the second and fifth ribs were removed. The tissue over the pericardium was incised and the adhesions of the visceral pericardium were manually separated. Excision of the pericardium was now performed. The inflammatory tissue in some places over the anterior surface of the heart was 1 inch (1.27 cm.) thick. The incision was then enlarged and as much as possible of the inflammatory tissue was excised: the anterior surface of the heart was freed from the parietal pericardium and exposed about 4 inches (10 cm.) in a vertical direction and about 3 inches (7.6 cm.) in the opposite direction.

Fig. 2 (case 5).—Case of purulent pericarditis and empyema, postpneumonic.

13. Mautz, F. R.: *Thoracic Surg.* 5: 612-628 (Aug.) 1936.

April 13 the child appeared to be clinically worse, respiration was labored, the pulse was weak, and the sclera were icteric. The child became gradually worse and died suddenly April 15.

The pathologic examination, by Dr. Levine, revealed numerous giant cells, early caseation necrosis and typical tubercle formation. Some sections showed a considerable degree of calcification. There was also an extensive degree of fibrosis. The diagnosis was tuberculous pericarditis.

Summary.—This patient was a very sick child when admitted to the Jewish Hospital, having had a previous admission in the

Fig. 3 (case 5).—Lateral view

CASE 3.—F. S., a white youth, aged 17, admitted to the Philadelphia General Hospital, Sept. 9, 1935, was referred by Dr. Boles for operation. The primary diagnosis was rheumatic pancarditis and rheumatic adherent pleuropericarditis. The chief complaint was pain over the heart, both shoulder joints and elbow joints. The patient had been discharged from the hospital Aug. 9, 1935, having recovered from an attack of acute rheumatic fever, during which acute pericarditis and pneumonia had developed. He had had three prior attacks of acute rheumatic fever but had been comparatively well, except for terrific palpitation and dyspnea, until ten days previous to admission, when he began to have severe precordial pain, which was greatly aggravated by any movement or deep breathing.

The significant facts in this case were as follows: temperature 102 F., pulse 130, respiration rate 32, blood pressure: 132 systolic, 40 diastolic. The patient appeared extremely ill; he was dyspneic and cyanotic in the lips and nail beds. There was no remarkable engorgement of the cervical veins. The heart was tremendously overactive, the entire bed literally vibrating from the tumultuous action. The entire front of the chest was extremely tender. The cardiac area of dullness extended deeply into the left axilla and there were signs of mitral and aortic valvular disease. The abdomen was tender. The liver and spleen were not palpable. There was no edema.

X-ray examination showed the transverse diameter of the heart to be slightly enlarged. The trachea was in the midline. There was slight enlargement of the left auricle. The heart was pulled over to the left.

The cardiogram showed notching of the T waves in leads 1 and 2 and slight notching of the ventricular complexes in the direct leads. Direct and indirect leads showed a slight left axis deviation.

Urinalysis was negative except for a trace of albumin. The blood count revealed hemoglobin 15 Gm., red blood cells 5,010,000, white blood cells 15,500, polymorphonuclears 80 per cent, lymphocytes 20 per cent. The Kahn reaction was negative. The blood sugar was 77 mg. and blood urea 13 mg.

A diagnosis of rheumatic pancarditis with pleuropericardial adhesions was made. Because of severe, intractable precordial pain that had persisted for more than three months, cardiomyolysis was advised.

Jan. 31, 1936, cardiomyolysis and pericardiectomy were performed under endotracheal gas, oxygen and ether anesthesia. A curved incision was made over the cardiac region. The fourth and

fifth ribs were exposed. The periosteum was reflected an 3 inches (7.6 cm.) was removed from the anterior portion of these ribs. The parietal pericardium was opened and numerous adhesions were found between the heart and this membrane. These were freed digitally and a section of anterior parietal pericardium about 10 cm. in diameter was removed and the wound closed.

The pathologic examination, by Dr. H. P. Custer, revealed dense fibrous tissue and a minor degree of residual chronic inflammation of nonspecific type, the exudate being largely lymphoplasmocytic; activity of rheumatic inflammation was apparently subsiding. The pathologic diagnosis was chronic proliferative pleuropericarditis.

Summary.—This case was one of typical rheumatic pericarditis. The patient was in the hospital for six months. Prior to his operation he complained almost continuously of severe precordial pain that required the constant use of narcotics. The operation, which was a Delorme decortication of the pericardium, entirely relieved the pain. After a stormy convalescence during which pneumonia developed, the patient made such a favorable recovery that he was permitted to leave the hospital and go home. About two months later he died suddenly while walking upstairs. A postmortem examination was not made.

CASE 4.—C. S., a Negro, aged 39, admitted to the Philadelphia General Hospital May 2, 1936, was referred by Dr. Boles for operation. The primary diagnosis was tuberculous pericarditis with effusion. The chief complaint was fever. The patient had been perfectly well until Sept. 4, 1935. He had been drinking heavily and he was suddenly seized with precordial pain and palpitation and dyspnea. The point of greatest pain was to the left of the sternum in the fifth interspace. Attacks of pain, palpitation and dyspnea recurred at irregular intervals, usually being induced by exertion, until April 31, 1936, when he had an unusually severe attack, the pain this time being referred to the back of the chest on the left side accompanied with fever. The pain lasted about two hours but the fever persisted and he was advised to come to the hospital.

On admission the patient appeared very toxic and had a temperature of 103 F. The pulse was 120 and respiration rate 25. The blood pressure was 110 systolic, 70 diastolic. Some dyspnea but no cyanosis was present. The heart was very much enlarged both to the right and to the left. The heart sounds were regular but somewhat muffled; no murmurs were detected. A fine "to and fro" friction sound was audible over the precordial area. A paradoxical pulse was present. There was engorgement of the veins in the neck. The liver and spleen were not palpable. There was no edema.

The urinalysis was negative. The blood count revealed hemoglobin 8 Gm., red blood cells 2,920,000, white blood cells 6,100, polymorphonuclears 82 per cent, lymphocytes 12 per cent, transitionals 6 per cent. The Kahn reaction was negative. Blood sugar was 123 mg. and blood urea 13 mg.

May 4, x-ray examination showed considerable widening of the transverse diameter of the heart and supracardiac shadow. The cardiothoracic ratio was 24 to 30.5. The entire cardiac silhouette had the "bottle" shape of pericarditis with effusion. The left diaphragm was obliterated and the right was in normal position. There was no evidence of tuberculosis in the lungs.

The cardiogram showed the ST intervals elevated in leads 2, 3 and 6 and depressed in lead 4. These alterations of the ST intervals were suggestive of pericarditis.

Fig. 4 (case 5).—Small amount of fluid in pericardial cavity. Parietal pleura much thickened. Heart small.

May 6, pericardial paracentesis was done and 270 cc. of bloody serous fluid was obtained. The patient was much more comfortable. Friction and splashing sounds over the precordium were still present, associated with high, irregular fever.

May 8, the cardiogram showed less evidence of pericarditis. There was depression of the ST intervals in leads 4 and 5. The previous slight elevation of these intervals in leads 2 and 6 was not present.

May 22, pericardial paracentesis was repeated, 450 cc. of bloody serous fluid was removed and 250 cc. of air was injected. Effusion was negative for the tubercle bacillus.

May 29, x-ray films showed no diminution of the size of the heart shadow. The patient now had a high, continuous fever and his general condition was failing. A guinea-pig that had been injected with a portion of exudate first removed was reported to be in a healthy condition after eight weeks. Because of the patient's downward course, pericardiotomy was advised. The diagnosis was pericarditis of unknown etiology, probably tuberculous.

Operation was performed June 2 under cyclopropane anesthesia. A curved 10 cm. incision was made with the convexity directed medially over the precordium. The skin flap was turned back, exposing the fourth, fifth and sixth left costal cartilages. The fifth and sixth costal cartilages were removed. Definite fulness was noted. An exploratory needle was introduced and a thick dark red fluid was obtained. The pericardium was incised and a large amount of the same fluid gushed out. The examining finger then noted that the surface of the heart was studded with small nodules. A small piece of parietal pericardium was incised for biopsy and its free surface had the same nodular appearance. No adhesions were noted anteriorly. The wound was closed with a rubber dam in the wound. The patient continued to do well after the operation. The temperature remained elevated for some time.

The pathologic examination, report by Dr. Custer, revealed that the pericardium was the seat of chronic proliferative inflammation characterized by tubercle formation and caseation necrosis. The surface was flecked with fibrin. The pathologic diagnosis was tuberculous pericarditis.

June 3, culture from the effusion yielded no growth. The smear was positive for acid-fast rods, morphologically Koch's bacillus.

June 19, x-ray examination revealed no difference in the size of the heart as compared to previous examinations. There were pleuropericardial adhesions to the left diaphragm.

The patient showed no improvement following the operation. He became gradually weaker and died August 5, two months after the pericardiotomy.

Summary.—This case proved interesting because of the doubtful character of the infection. Although tuberculosis of the pericardium was suspected, inoculation of a guinea-pig showed no changes eight weeks afterward. The fourth, fifth and sixth costal cartilages were removed. When the pericardium was incised and the finger inserted in the sac, numerous elevations were felt. Because there had been no positive evidence of tuberculosis, it was thought that the pericarditis might be of a malignant type. A piece was excised. Dr. Custer, the pathologist, reported one tubercle found and some caseation necrosis. The patient finally died of miliary tuberculosis two months following the operation. Had we had positive evidence prior to operation that the patient was tuberculous, we never would have resorted to drainage. Tuberculous effusions in any part of the body should not be drained because of the danger of mixed infection.

CASE 5.—J. M., a white man, aged 39, admitted to the Philadelphia General Hospital March 26, 1936, was referred by Dr. Boles and Dr. Hubley R. Owen for operation. The primary diagnosis was lobar pneumonia type I, pneumococcal bacteremia, and pneumococcal pericarditis with purulent effusion. The chief complaint was cough and pain in the chest. The patient was well until March 21, 1936, when a high fever and a cough developed following by a chill a few days later. He then complained of a severe sharp pain, which was aggravated by coughing over the entire right side of the chest. On admission four days after onset of illness the significant conditions were as follows: lobar pneumonia, the right, middle and lower lobes being involved; temperature 102 F., pulse 120, respiration rate 35; blood pressure 120 systolic, 60 diastolic. The pneumonia was type I and was associated with infection of the blood

stream. Slight cyanosis and dyspnea were present. Herpes labialis was present. Examination of the heart revealed nothing unusual.

Urinalysis was negative except for albumin. The blood count revealed white blood cells 47,900, polymorphonuclears 88 per cent, lymphocytes 4 per cent, large mononuclears and transitionals 8 per cent. The Kahn reaction was negative; blood sugar was 134 mg. and blood urea 25 mg.

The patient was tested for serum sensitivity and, being negative, was given polyvalent antipneumococcus serum. Serum was administered at intervals until March 27, apparently with some improvement.

March 28, pericardial friction was noted, the patient complaining of severe precordial pain. A paradoxical pulse was present.

March 30 a cardiogram revealed considerable elevation of the ST intervals in leads 1 and 2. While the origin of the ST line was slightly away from the base line in leads 4 and 5, it was more marked in lead 6. "These are the findings we have encountered in pericarditis. The usual etiology in the instances in which we have seen these changes has been pneumococcal, uremic or rheumatic. We have so far not seen the change to a marked degree in tuberculous pericarditis."

March 31 the cardiac area of dullness increased to the left. There was slight cyanosis but increasing dyspnea and weakness. The leukocyte count, which previously had dropped to 34,600,

was now 58,000. A diagnosis of acute suppurative pneumococcal pericarditis was made. X-ray examination revealed pericarditis with effusion. Pericardial paracentesis was done and 15 cc. of a yellowish green exudate was secured. Auricular fibrillation was present.

April 3 there was pericardial effusion: cells per cubic millimeter, 9,600; polymorphonuclears, 98 per cent; lymphocytes, 1 per cent; endothelial cells, 1 per cent; gram-positive diplococci.

April 3 the cardiogram revealed auricular flutter present, with a 2:1 and 3:1 auriculoventricular heart block. The ST intervals were elevated in leads 1 and 2.

Paracentesis of the precordium was repeated and 330 cc. of exudate recovered with immediate relief of dyspnea and weakness.

April 4 paracentesis of the precordium was repeated and 540 cc. of purulent exudate was removed. Later in the day 720 cc. of exudate was removed.

April 5, 120 cc. of purulent exudate of thicker consistency was removed. X-ray examination revealed still considerable fluid present in the pericardial sac. Pericardiotomy was advised.

April 6, under local anesthesia, a curved incision was made over the lower portion of the sternum. A flap of subcutaneous tissue and skin was turned to the side. The fourth and fifth ribs were removed 2 inches from the sternum, and the pericardium was exposed. Aspiration revealed pus. An incision was made in the pericardium and a large amount of pus was obtained. Pus drained continuously from the pericardial sac. Irrigation was instituted with various antiseptic solutions, including diluted solution of sodium hypochlorite. At times there seemed to be a diminution in pus, but nevertheless it continued in varying amounts.

April 7 the T waves were inverted in leads 1 and 2. "In the presence of pericarditis this finding is to be interpreted as due to the outer portion of the myocardium, the result of extension of the pericardial inflammatory process."

Fig. 5.—No fluid in pericardial cavity. Fluid level in right pleural cavity.

April 10, leukocytes numbered 10,900, with polymorphonuclears 76 per cent, lymphocytes 6 per cent, monocytes 18 per cent and eosinophils 2 per cent.

April 14 the sutures were removed. The Dakin tube was removed.

April 21, x-ray examination revealed no fluid demonstrable in the pericardial sac.

April 29 there were signs of empyema in the left side of the chest. Under local anesthesia a trocar and cannula were introduced in the eighth interspace of the posterior axillary line on the left side and pus was obtained.

April 30, 1,700 cc. of purulent exudate was removed from the left pleural cavity.

May 3 the patient seemed to be holding his own, with improved drainage and daily transfusions. Suppurative pneumonitis was suspected on the right side, confirmed by x-ray examination.

The course was rapidly downward from this time on and the patient died May 7.

Summary.—This case is representative of an acute suppurative type of pericarditis, complicating lobar pneumonia. The operation had to be done with the patient in a sitting position under local anesthesia. He did not remember anything concerning his transfer to the operating room or the operation. After excision of the fourth and fifth costal cartilages the pericardium was incised and a large amount of pus exuded. The patient had a stormy convalescence requiring later a thoracotomy, closed method, for pleural empyema.

Pericardiotomy was definitely indicated in this case because of the presence of a large suppurative effusion in the pericardial sac. The patient withstood the operation well and showed striking improvement following it; despite a subsequent thoracotomy for a left sided encapsulated empyema twenty-four days after the pericardiotomy, it was thought he might recover. The development of interlobar empyema and suppurative pneumonitis in the right lung was overwhelming and he died one month following the pericardiotomy.

Postmortem Examination.—The heart weighed 400 Gm. The parietal pericardium was greatly thickened, measuring from 5 to 10 mm. in places. Thickening was due to fibrous-like tissue, presumably recently organized inflammatory exudate. The openings of the vena cava seemed to be constricted by adherent and greatly thickened surrounding pericardium. There was no evidence of hypertrophy. The histologic diagnosis was acute and organizing pericarditis, myocardial degeneration and pericardial tamponade due to a thickened pericardium.

The right lung showed obliterative fibrous pleural adhesions and encapsulated empyema at the base with interlobar empyema between the middle and lower lobes. The left lung showed obliterative fibrous pleural adhesions with encapsulated empyema at the base.

CONCLUSIONS

Three patients in the Philadelphia General Hospital and one each in the Mount Sinai and Jewish hospitals had been sick from several months to several years. The cases presented illustrate the necessity for prompt radical drainage in suppurative pericarditis, of nonsurgical intervention in tuberculous pericarditis and of earlier operation in chronic mediastinopericarditis.

A close cooperation of the internist, roentgenologist and surgeon may be expected to lead to greater accuracy in the diagnosis of pericarditis and its complications and thereby to early effective surgical treatment in properly selected cases.

INTRA-UTERINE RESPIRATORY MOVEMENTS OF THE HUMAN FETUS

FRANKLIN F. SNYDER, M.D.

AND

MORRIS ROSENFELD, M.D.

BALTIMORE

The present observations represent an attempt to determine whether the human fetus shows spontaneous respiratory movements within the uterus or whether, as is generally believed, fetal apnea persists throughout prenatal life until interrupted at birth by the first breath.

In recent experiments with rabbits, cats and guinea-pigs, we¹ found that, instead of a state of prolonged apnea before birth, the fetal respiratory system shows long periods of automatic activity. When one now

Fig. 1.—Alveoli of fetal lung at term showing cells and debris introduced with the current of amniotic fluid entering the lung as a result of intra-uterine respiratory movements. The rabbit fetus was observed to be breathing within the amniotic fluid. The trachea was clamped and fixation in solution of formaldehyde completed within the uterus to avoid the breathing of air. The striking dilatation of the alveoli is related to intra-uterine respiration and is entirely independent of breathing air; $\times 300$.

turns to the human fetus, the question is whether or not man is like the other species studied or stands apart.

Observations of the fetal movements transmitted through the abdominal wall were made in a series of women near term. With the woman in a recumbent position on her back, careful inspection of the abdomen was carried out. Apart from the general body movements of the fetus there could be recognized unmistakably spontaneous fetal movements, which continued at

a regular rhythm for many minutes. The movements were integrated in a pattern that was characteristic of respiration. They were identical with the rhythmic fetal movements that are seen in other species in which there is available experimental proof of their respiratory nature.

In order to obtain objective data concerning the rate and pattern, the movements were recorded by aid of motion pictures. Analysis of these records showed a distinctive type of excursion of the abdominal wall, which occurred with regular rhythm. The excursions were clearly distinguished as independent movements superimposed on those resulting from maternal respiration. Differentiation was easily made in view of the marked difference in rate, the ratio being approximately three fetal respirations to one of the mother. Pulsations transmitted from the abdominal aorta were taken into consideration as a source of confusion but were readily eliminated. Record of the maternal pulse taken simultaneously with the respiratory movements showed that they were completely dissociated in rate. In addition, the gross characteristics, such as localization and amplitude, of the excursions permitted unequivocal differentiation.

Two chief types of fetal respiratory movements were observed. One type is characterized by a rapid rate, i. e., about 60 per minute, and a shallow excursion. The other type, which is less commonly seen, appears as a sudden deep excursion recurring at a slower rate; i. e., 15 per minute. The former resembles thoracic respiration, while the latter resembles abdominal breathing. These two types of movements were also easily distinguished in animal experiments in which the fetus of the rabbit could be directly viewed through the transparent uterine wall.

In late pregnancy the woman herself may become aware of rhythmic fetal movements, in contrast to irregular, general body movements. Patients have voluntarily made inquiry regarding the significance of fetal movements which they described as a "flutter" and which occurred usually soon after lying down and persisted for a period of minutes. We were easily able to correlate the patient's subjective description with the actual observation of transmitted fetal respiratory movements.

A clue to the significance of fetal respiration is afforded by the finding of cells and debris characteristic of amniotic fluid scattered throughout the lungs during intra-uterine life.² In figure 1 the contents are shown of alveoli of the lung of a rabbit fetus that was observed to be breathing within the uterus. That the breathing of amniotic fluid is a normal function of fetal respiration may be clearly illustrated by experiment.³ In a rabbit in which the uterus was exposed by laparotomy, india ink was injected into the amniotic sac of fetuses that were seen to be breathing, as well as in littermates in which breathing was inhibited by a previous injection of pentobarbital sodium. Examination of the lungs one or more minutes after addition of the ink to the amniotic fluid showed the carbon particles in the alveoli throughout the lungs of the fetuses which were breathing, while the lungs of apneic fetuses contained none (figs. 2 and 3).

COMMENT

Respiration is not initiated in the child at birth but extends far back into embryonic life. Instead of a state of complete apnea during intra-uterine life, the human fetus shows spontaneous respiratory movements for periods lasting many minutes.

The capacity of the human fetus to show respiratory movements within the uterus for brief intervals was recognized by Schultze.⁴ Ahlfeld⁵ noted that the human fetus exhibits rhythmic respiratory movements in the latter part of pregnancy. Weber,⁶ a student of Ahlfeld, published a full description with tracings of excursions transmitted to the abdominal wall of the mother. Reifferscheid⁷ confirmed these observations. Both Ahlfeld and Reifferscheid stated that fetal respiration does not normally result in the entrance of amniotic fluid into the alveoli. Other investigators among his contemporaries vigorously disagreed with Ahlfeld's inference that the movements which were seen indirectly through the abdominal wall represented fetal respiration.⁸ In more recent years Ahlfeld's view has been disregarded because at operation direct observation of the fetus within the uterus failed to reveal rhythmic respiratory movements. Apnea has been regarded as

Fig. 2.—A, lung of apneic fetus. B, lung of fetus breathing within the uterus. In both fetuses india ink was introduced into the amniotic fluid twenty minutes before the animal was killed. Entrance of stained amniotic fluid into B and the normal appearance of A demonstrate that intra-uterine respiratory movements result in the breathing of amniotic fluid; $\times 1/2$

the normal state of the fetus,⁹ and the cause of the initiation of respiration has been sought in the changes attending birth.¹⁰

Respiratory failure of the new-born, or asphyxia neonatorum, must be regarded as a suppression of previous activity rather than failure of some new mechanism to begin functioning at birth. In the apneic new-born child the question is not what causes the first breath but rather what factors have been superimposed to suppress the continuation of respiratory movements. With regard to the causes of respiratory failure, it may be emphasized that the fetal respiratory system before birth has been demonstrated to have a peculiar sensitivity to the depressant effect of anoxemia and narcosis.¹ Both of these factors belong to the period

preceding delivery. To deal with them at that time by efforts to maintain adequate oxygenation,¹¹ and caution in the choice and use of anesthetic agents would be more effective than later attempts at resuscitation.

The aspiration of amniotic fluid is not an accidental complication of labor but must be viewed as a normal consequence of fetal respiration. The respiratory movements are responsible for a tidal flow of amniotic fluid into the lungs, which thus affords a mechanism for the dilatation of the future air passages. Fetal respiration thus aids in the structural differentiation of the normal lung.

The normal development of the alveoli may be complicated by the presence of amniotic fluid containing debris of excessive amount or abnormal type. A mechanical obstruction of bronchioles brought about during embryonic life may interfere with the normal

Fig. 3.—Microscopic view of lung B, showing the extensive distribution of carbon particles throughout the alveoli; $\times 80$.

flow into the lung of amniotic fluid and result in incomplete dilatation of alveoli; i. e., atelectasis. Certain types of debris such as cells, meconium and sebaceous matter may be injurious not only as foreign bodies but also as chemical irritants.

In view of the rapid exchange of fluid between the pulmonary alveoli and the amniotic sac, bacterial contamination exposes the alveoli to immediate invasion by a current of infected fluid. The pathogenesis of intra-uterine pneumonia may be clearly reconstructed in many cases as a complication of normal intra-uterine respiration.

CONCLUSION

Two types of injury of the lung before birth may be attributed to breathing of abnormal amniotic fluid; namely, the entrance of foreign debris resulting in obstruction and irritation, and the entrance of foreign organisms producing infection.

TWO CASES OF STREPTOCOCCIC MENINGITIS

TREATED SUCCESSFULLY WITH SULFANILAMIDE AND PRONTOSIL

MAX H. WEINBERG, M.D.

RALPH R. MELLON, M.D.

AND

LAURENCE E. SHINN, Ph.D.

PITTSBURGH

Reports from European laboratories which have been confirmed by one of us have resulted in our employment of this new chemotherapeutic treatment of the more severe types of hemolytic streptococcus infection. We also wished to study its effects in comparison with that of a new type of serum treatment which has been used successfully by us for nearly a decade and which was reported in summary form recently. The present paper will be devoted to the report of two cases of meningitis, which by their nature and severity we deem to have important evidential value.

REPORT OF CASES

CASE 1.—*History.*—C. S., a white youth, aged 17, admitted to the hospital Aug. 31, 1936, complained of headache, "running ear" (left), pain, fever, nausea and vomiting. He was delirious. August 28, following a swim in the river, an acute otitis media had developed. The earache became worse. Two days later fever set in. The next day nausea, vomiting and a severe headache developed, most marked over the eyes and left parietal area. The patient had difficulty in recognizing members of the family. On the day of admission, he became dizzy and complained of amblyopia.

Examination.—The boy was poorly nourished and stuporous. He had a high fever (103.6 F), a purulent discharge from the left ear, a gray purulent membrane lining the posterior pharyngeal wall, a few palpable cervical glands, and tenderness below the left mastoid.

Neurologic examination revealed a slightly obscure right disk with slight elevation and congested vessels, weakness of the left internal rectus, slight weakness of the left facial muscles, rigidity of the neck, an increase of the right radioperiosteal reflex, diminished abdominal and cremasteric reflexes, an increased right suprapatellar reflex and slightly increased right achilles reflex, and a suggestive Babinski sign on the right.

A diagnosis of meningitis and otitis media with mastoid involvement was made. A mastoidectomy was performed the same night by Dr. U. F. Rohm. He noted that when the mastoid cavity was opened much pus under pressure and necrotic cells were found. The cavity was cleaned of all denuded tissue.

The first lumbar puncture was done August 31. The cell count was 750. Fluid culture showed hemolytic streptococci.

TABLE 1.—Treatment Used

	Route	Dosage
Prontosil	Intramuscular injections	5 cc. three times a day for three days
		5 cc. twice a day for one day
		5 cc. once a day for two days
Sulfanilamide	Oral	One tablet six times a day for five days

Twenty-four hours after the operation the patient was feverish, irrational, restless and perspiring profusely. He complained of diplopia.

Prontosil² treatment was instituted September 1 (table 1). *Course.*—On the second day of the treatment, the temperature fell 3 degrees. The patient was a little more rational, although still stuporous. On the fourth day he showed marked improve-

From the Neurological Service and the Institute of Pathology, Western Pennsylvania Hospital.

1. Dr. James McLallen in whose nose and throat service the case occurred, gave us the opportunity to treat and study this case.

2. The prontosil used was the disodium salt of 4-sulfamidophenyl-2-azo-2'-acetylamino-1'-hydroxynaphthalene-3', 6' disulfonic acid.

ment. Spinal fluid, however, still showed 850 cells, mostly polymorphonuclears, and the organisms were present on direct smear. The culture, however, grew only one or two colonies on a blood-agar plate, despite a rather large inoculum. On the fifth day he no longer complained of diplopia but was still somewhat drowsy.

Two days later, the rigidity of the neck had practically disappeared.

The next day there was again a slight rise in temperature, and then it fluctuated for several days between 100.6 F. and normal.

The patient was discharged September 15, a little more than two weeks after admission, fully recovered. A report from his physician Feb. 23, 1937, stated that the boy felt well but that he was troubled occasionally with diplopia and dizziness.

TABLE 2.—Treatment Used

	Route	Dosage
Prontosil	Intramuscular injections	5 cc. four times a day for two days
Sulfanilamide	Oral	5 grains every four hours for two days 5 grains every two hours for two days 10 grains every two hours for two days
Sulfanilamide	Rectal (dissolved in water)	15 grains every six hours for two days 10 grains every six hours for two days

On reexamination, Feb. 25, 1937, the patient complained of suffering with occasional diplopia and dizziness. He was doing well in his school work. On examination only a slight nystagmus to the left was found.

Laboratory Studies.—The first urine examination, Sept. 1, 1936, showed albumin 2 plus, from six to eight white blood cells per high power field, and occasional granular casts. The urine was examined daily. By the fourth day the urine was essentially normal.

The first blood count, August 31, showed a fairly normal red count and hemoglobin, but the white blood cells were 19,500, and the polymorphonuclears, 90 per cent. On the next day the white cells numbered 18,000, and two days later 11,650 and polymorphonuclears only 79 per cent. The final white cell count September 9, was 11,000. The Kahn test on the blood was negative.

Roentgen examination of the left mastoid showed a slight haziness over the entire mastoid, with some increase in the thickening of the cell walls but no definite evidence of cellular destruction.

CASE 2.—History.—M. B., a white girl, aged 10 years, admitted to the hospital Jan. 17, 1937, complained of discharging right ear, severe headache, vomiting and fever. She was stuporous and markedly restless. Acute right otitis media developed in the spring of 1936, requiring paracentesis twice. Except for a slight discharge from the ear, which persisted until August, the patient felt well.

Late in December the patient contracted a cold, and discharge from the ear reappeared with marked earache and slight fever. The discharge persisted until the present. One week prior to admission, intermittent headaches developed but not enough to interfere with her activities.

Jan. 15, 1937, she began to complain of pain in the neck and headache. In the evening she vomited two or three times, and this was followed by a rise in temperature. The ear began to discharge profusely. She vomited about every fifteen minutes during the night and became very restless. The fever continued to be high the next morning. She was delirious at times. On the day of admission the condition became much worse.

Examination.—The patient looked moribund. She was extremely restless and not aware of her surroundings. The left eyelid was practically closed. The right cheek was flushed. The heart rate was rapid, but no irregularities or abnormalities were noted. The patient was in stupor. The left pupil was dilated to the extreme and did not react to light. The right pupil was dilated but reacted well. The left disk was slightly hazy. Speech was lost. All deep reflexes were suppressed. The Babinski sign was present on the left. A bilateral Kernig sign was pronounced, and there was marked rigidity of the neck. The temperature (rectal) was 106.6 F., the pulse 140 and the respiration rate 70.

The diagnosis was basal meningitis, streptococcic.

Lumbar puncture was done at once. The fluid was turbid, under marked pressure, and spurting out of the needle. The cell count was 3,000 per cubic millimeter, mostly all polymorphonuclear leukocytes. Streptococci were in chains; about eight chains to the high power field were seen.

Prontosil and sulfanilamide treatment was immediately instituted (table 2).

Course.—The patient's condition remained practically unchanged during the first forty-eight hours except that ballism of the left arm and leg developed, and the left lid closed completely on the second day. The patient was found to have dysphagia. The deep reflexes of the left extremities were increased. In forty-eight hours the child seemed to be more aware of her surroundings. On the third day there were slight changes in the disks, the margins were blurred and the veins were congested. The rigidity of the neck was diminished. The deep reflexes on the right reappeared. The Babinski sign on the left disappeared. In another three days the patient was much clearer, and the dysphagia commenced to improve. Speech, however, did not return. An otologic examination revealed only a puncture but no discharge. On the ninth day after treatment was instituted, a slight yellowish tint of the skin was noted and a blood count was ordered.

Examination of the blood suggested a moderate secondary anemia, and sulfanilamide was discontinued the next day, January 27. Supportive treatment was given.

Speech commenced to return but was typically bulbar. Three days later the patient could carry on a conversation, but speech was still bulbar. The dysphagia practically disappeared. In three more days, slight movement of the left upper lid was noticed. The patient was discharged February 9, twenty-three days after admission, in fairly good condition. It was the first time the patient could co-operate fully.

The discharge note reads: "Speech is much better. The patient states that she feels fine. Left third nerve paralysis is still complete. There is slight weakness of the left side of the face. The tongue is tremulous and deviates slightly to the left. The grip of the left hand is somewhat weak. The deep reflexes are within upper normal limits. Abdominal reflexes are normal, except that the upper left is diminished. No rigidity, no Kernig or Babinski sign.

On reexamination, March 27, ptosis of the left lid had disappeared, but the left pupil reacted only to sympathetic stimulation. Otherwise, neurologic examination was essentially negative.

The first specimen of urine showed 2 plus albumin and from 18 to 20 white blood cells per high power field. The next daily specimen showed less albumin and cells, and in about a week the urine cleared up.

The first red blood count, January 18, was normal, but the white blood cell count was 18,900, and the polymorphonuclear leukocytes constituted 88 per cent. The second count showed a slight reduction in the red cell count and hemoglobin. The white blood cells were only 14,000, and the polymorphonuclears 77 per cent. The third blood examination showed the same red cell count, but the white blood cells had again risen to 20,300, and the polymorphonuclears were 82 per cent. There were also three nucleated red cells, and numerous red cells showed polychromatophilia.

Fig. 1.—Culture made with half a drop of first spinal fluid specimen, showing numerous colonies of hemolytic streptococci.

The next day, January 26, hemoglobin was below 70. Blood smear showed moderate anisocytosis with numerous microcytes. There was an occasional nucleated red blood cell. Numerous cells showed polychromasia.

The next three examinations done after discontinuance of the medication showed gradual improvement in the blood picture.

Spinal fluid examination was done every two days (table 3).

COMMENT

Even though a case of recovery of streptococcic meningitis by other methods of treatment is occasionally reported in the literature, the hopelessness of this con-

Fig. 2.—Culture made with five drops of second spinal fluid specimen, showing no growth.

dition is recognized by all writers on this subject. Thus Gray,³ including his own case, could find only sixty-one cases of recovery in the years 1901-1935. He considers it a "usually fatal disease." Zeligs⁴ states: "Recovery from streptococcic meningitis rarely occurs. Kolmer stated that the mortality is almost 100 per cent. In a series of thirty-three cases from the University of Michigan Hospital, there was only one recovery. During the past fourteen years there have been fifty-seven verified cases of streptococcic meningitis in the wards of the Cincinnati General Hospital." In this series only one recovered.

Caussé, Loiseau and Gisselbrecht⁵ are the only ones to report a case of meningitis due to hemolytic streptococci treated with protosil. Their case was apparently not of a very severe type. The highest cell count was 92, but a direct fluid smear showed short chains of streptococci, and the culture was positive. The patient recovered.

It is because of the extremely high mortality in streptococcic meningitis that we consider the successful result of two consecutive cases—the only ones we had opportunity to treat—of great significance and of sufficient importance to report promptly, so that the profession generally will try this method in as large a group of cases as possible.

Of the two cases, the second is the one that merits the greater attention. The patient was practically moribund when she was admitted. From both the clinical and the bacteriologic standpoint the patient appeared to be doomed. Dr. Hadley, chief of bacteriology at the institute, made the following comment in his report: "During the past two years at this hospital, no cases of streptococcic meningitis showing such a large number of organisms per field in the direct microscopic examination has lived for more than twelve hours after the spinal fluid was taken." Clinically we felt equally despondent. The child had marked bulbar involvement, and the dysphagia was almost complete. We think that the successful outcome in a case so severe is nothing short of dramatic.

There is no reasonable doubt that a noteworthy bacteriostatic and probably a bactericidal effect of the spinal fluid is present. It is particularly clear cut in the second case, in which no growth of streptococci occurred after treatment, despite the fact that ten times the original inoculation was employed. The relative sparsity of streptococci present in the smears supported this finding.

Moreover, Bambas of this laboratory in a series of carefully conducted bacteriostatic tests found that when 125 of the patient's streptococci were incubated in the patient's fresh spinal fluid about half of them refused to grow after eight hours incubation of the fluid at 37 C. After twenty-four hours none grew. This was in marked contrast to normal serums when seeding of 125 hemolytic streptococci often multiply in twenty-four hours to 2,000.

Of the ultimate fate of these inhibited or killed organisms in the human being little is known. In our studies of several hundred mice we have found no evidence that they were phagocytized either by the polymorphonuclears, the mononuclears or the reticulo-endothelial system of the liver or spleen (Dr. Paul Gross).

These observations are not in accord with the observations of Long and Bliss, who on the basis of

TABLE 3.—Spinal Fluid Examinations in Case 2

	Pressure	Cell Count	Globulin	Direct Smear	Culture
1/17/37	Fluid spurted out	3,000 (polymorpho-nuclears)	Organisms present; chains	Positive
1/19/37	Slight	2,500 (polymorpho-nuclears)	3 plus	Present	Negative
1/21/37	Normal	1,450	2 plus	Absent	Negative
1/22/37	Normal	150 (70% polymorpho-nuclears; 30% lymphocytes)	1 plus	Absent	Negative

appearances in one mouse and its companion control believe that phagocytosis plays an important rôle. Differences in strains may conceivably account for the discrepancies.

The question of dosage and method of administration cannot be answered definitely as yet. The drug does not seem to be very toxic, so it is rather safe to use. Attempts at standardization of dosage are already being made. We have given normal individuals as much as 4 Gm. a day and our type III pneumonia patients who have shown a remarkable response (about 75 per cent recovery) have often received as much and sometimes more, daily.

Colebrook's bacteriostatic in vitro tests indicate that 1:10,000 dilution of the drug is an optimum concen-

tration in the serum, and now that they have recently made available a quantitative test for the substance in the blood, the matter of the dosage promises to be worked out with more precision.

As to the rule of administering the drug, all workers agree that when swallowing is difficult the drug should be given intramuscularly. Long and Bliss quote Schwenker as having used an 0.8 per cent solution of sulfanilamide in physiologic solution of sodium chloride intrathecally in the treatment of streptococcal meningitis. Causse Loiseau and Gisselbrecht used the drug intravenously. In view of our experience in these two cases we are inclined to think that such a hazardous form of therapy as intrathecal administration should be used only as a last resort. We have overcome the difficulty of the patient's inability to swallow the tablet by administering the drug by rectum.

Therapy should be started immediately. The bacteriostatic observations of the English workers estimate that it takes at least forty-eight hours before such effects can be obtained in the serum; and because of this the treatment should be instituted promptly. In our second case we started the treatment in one hour and twenty minutes, the time that it took to complete the neurologic examination, the lumbar puncture and the microscopic examination of the fluid after admission of the patient to the hospital.

TOXIC EFFECTS

The only possibly toxic effects noticeable were in case 2. On the ninth day of treatment the patient's skin took on a yellowish tint. Blood examinations revealed a moderate progressive decrease of the red cells and hemoglobin, and there were other changes such as a few nucleated red blood cells, polychromasia and moderate anisocytosis. With the discontinuance of the drug the condition of the blood improved. None of the other workers, who have treated many patients with streptococcal infections, noted such a change. It is possible that this is an isolated phenomenon in this particular case.

CONCLUSIONS

1. Two severely ill patients with streptococcal meningitis, one of them of the highest severity, were treated successfully with sulfanilamide and prontosil.

2. One patient recovered fully, but the second still has a partial paralysis of the third nerve.

3. In view of our clinical experience with the drug, it is urged that it be used promptly in cases of streptococcal meningitis.

Pleurisy with Effusion.—We regard pleurisy with effusion as a reinfection form of tuberculosis which develops from the focus of the first infection. The tissues are highly sensitized to tuberculo-protein through the development of the primary lesion, and bacilli are easily transmitted to the lymph channels of the visceral pleura from the lesions, which often lie near the periphery of the lung. The appearance of fluid in the pleural cavity is usually preceded by pain, and friction sounds may be elicited for a few days. When effusion begins to make its appearance and ordinary anteroposterior roentgenograms will not demonstrate it with certainty, Rigler's posture method is of great aid. When the effusion becomes larger, it is usually possible to recover tubercle bacilli from smears of centrifugated fluid or by culture and inoculation methods.—Myers, J. A.; Diehl, H. S.; Boynton, Ruth E., and Trach, Benedict: Development of Tuberculosis in Adult Life, *Arch. Int. Med.* 59:1 (Jan.) 1937.

INTERMITTENT VENOUS HYPEREMIA IN THE TREATMENT OF PERIPHERAL VASCULAR DISEASE

GEZA DE TAKATS, M.D.
FORD K. HICK, M.D.

AND
JOHN S. COULTER, M.D.
CHICAGO

In analyzing the mechanism by which alternating suction and pressure¹ exert their effects on the course of obliterative arterial disease, we found that in four types of apparatus examined there occurred an intermittent venous stasis in the limb under treatment. The cuff attached to the thigh constricts the limb during the phase of suction and releases it during the phase of positive pressure. The phenomena of reddening of the toes and filling of the veins, the rise of surface temperature and the increased mobility of the toes, all of which can be observed as objective changes produced by passive vascular exercise,¹ can be reproduced by intermittent venous compression. It is our purpose in this communication to examine this factor, study its physiologic aspects and report on its clinical use.

THE EFFECTS OF VENOUS CONSTRICTION

In the beginning of this century, surgical thought was greatly influenced by the writings of Bier² on venous hyperemia. Three and a half decades later, as a summary of his vast clinical experience, he reviewed his observations and those of his school in an article of monographic proportions.³ Bier undoubtedly established the following facts on the basis of experimental and numerous clinical observations: (1) Venous hyperemia produces a reactive hyperemia independent of nervous impulses, (2) mild venous stasis maintained for one hour produces more benefit than arterial constriction of the same duration, (3) reactive hyperemia may be produced when the larger vessels are occluded or cut as in pedicled flaps, whose pedicle had just been severed, and (4) reactive hyperemia ensues through the accumulation of metabolites and the filling and stretching of minute vessels.

It seemed necessary to restate Bier's essential observations in detail, because they are tucked away in a mass of speculative and teleological dissertations and nowhere summarized. Later workers, with accurate physiologic methods, have confirmed all these early views. Thus, Lewis and Grant⁴ think that a slowly diffusible histamine-like substance accumulates in the tissue spaces when the arterial supply to a limb is occluded, causing an active dilatation of all the vessels. A similar reaction occurs, however, when venous pressure is raised, the optimum being 80 mm. of mercury. They stated that the longer the occlusion and the higher the environmental temperature, the more vasodilatation was produced. Differing from this statement, Gold-

From the Department of Surgery, University of Illinois College of Medicine and the Department of Physical Therapy, St. Luke's Hospital, Chicago. Aided by a grant of the Council on Physical Therapy of the American Medical Association and the Graduate Research Fund of the University of Illinois.

blatt⁵ found in dogs that hyperemia following vascular occlusion was maximal after 120 seconds and that longer occlusions diminished the reaction. He also made an observation, which is important from our point of view, that the reactive hyperemia diminishes after the second occlusion, unless a large enough interval (90-120 seconds) is allowed to elapse between the reactions. The shorter the interval between the two occlusions, the greater the diminution of the reactive hyperemia. When the interval was shortened to fifteen-twenty seconds, the reaction was abolished. This refractory stage is longer, the greater the preceding reaction. Recently Huggins, Blockson and Wilson⁶ gave an exhaustive review of the literature and found that mechanical obstruction to arterial flow resulted in a decrease and, after release, in an increase in temperature. The greatest increments of heat occurred in the bone marrow. In studying the effect of venous constriction they did not find such a reactive hyperemia as to be measurable by an increase in temperature, although this may be detected by measurements of blood flow.

Whether this accumulating vasodilator substance is a single histamine-like substance or, as Krogh⁷ and Bier⁸ believe, a multiplicity of substances is here beside the point. Frey⁹ believes that the increased acidity, which occurs in the anoxic tissue, activates the circulating pancreatic hormone, which is present in the blood but is in an inactive state.

Less interest has been focused on effects other than those due to the accumulation of metabolites following venous constriction. Yet the mechanical effect of filling and stretching of the venules and capillaries, when arterial inflow is unobstructed but venous backflow is interrupted, is obvious. There is a biphasic increase in limb volume when a blood pressure cuff is applied at a pressure which is below diastolic pressure.⁹ During the first phase, the volume of the compressed extremity rises for fifteen to twenty seconds quite rapidly. This is due to the collection of blood in the venules and capillaries and ends when the venous pressure becomes equal to cuff pressure. The capillaries are able to contract against internal pressures of from 50 to 60 mm. of mercury. When venous pressure is raised to 90 or 100 mm. of mercury, petechial hemorrhages may occur. The second phase is due to a stretching of the vascular bed and to tissue edema. Then filtration pressure in the capillaries will be raised over the osmotic pressure of the blood. This ratio is disturbed in limbs suffering from arterial obstruction when the hydrostatic pressure falls below the osmotic pressure, so that circulation will not take place from the capillaries to the tissues.¹⁰ This increased filtration pressure may well explain the temporary beneficial effects of concomitant venous ligations when the artery is obstructed.¹¹

The elevation of venous pressure raises capillary pressure to an equal or even slightly higher level.

Landis¹² has summarized our knowledge and added fundamental data on capillary pressure and capillary permeability. Capillary blood pressure at rest depends on arterial tone, venous tone, posture and temperature. The average capillary pressure is 32 mm. of mercury in the arterial limb and 12 mm. of mercury in the venous limb. When skin temperature is elevated to 42 C., this pressure can be raised to 60 mm. in the arterial and 45 mm. of mercury in the venous limb. A venous pressure of 60 mm. of mercury raises capillary pressure as high as 42 C. of heat or even higher but without the increased oxygen consumption of the cells. With regard to the rate of edema formation, Landis found that a venous pressure of 80 cm. of water (about 60 mm. of mercury) causes fluid to accumulate in the tissue spaces at only 0.20 Gm. per minute per hundred cubic centimeters of tissue. When the veins are obstructed by a cuff placed on the thigh of a dog, lymph flow is markedly increased and the lymph becomes more dilute. A pressure of 60 mm. of mercury maintained for ten minutes raised the lymph flow to 0.54 cc. from 0.1 cc., when the animal stood quietly. Exercise of any sort would quickly increase it to an even greater volume.

Capps¹³ has recently studied the tonus of the venules and capillaries by measuring the increase of the volume of the hand following different cuff pressures and temperatures. Significant is his finding of a marked atony of the venocapillary system shortly after sympathectomy, which was manifested by a great increase in limb volume after applying a pressure of 20 mm. of mercury.

There is finally the effect of the slowing of the circulation on the utilization of oxygen to be considered. If the inflow of oxygenated blood is not diminished, the high intravascular tension of oxygen should lead to an increased saturation of the tissues. And truly, when strips of muscle from guinea-pigs were placed in a Warburg apparatus, their oxygen consumption diminished from one fourth to one half of the normal level after venous constriction, because they had more than the normal concentration of oxygen to start with, whereas after arterial constriction these muscle strips consumed twice as much oxygen as in the resting state, thus explaining Bier's "blood thirst" of the anemic tissue.¹⁴

In considering the oxygen utilization of the tissues during a slowing of the circulation, the following factors have to be considered: by raising the carbon dioxide tension, more oxygen is evolved at low oxygen tension; at lower oxygen tensions the blood gives off more oxygen. On the other hand, new oxygen is not transported rapidly enough to maintain its optimum tension in the tissues. Such a state occurs during venous constriction, a typical "stagnant anoxia" of Bancroft, which is characterized by a normal arterial oxygen tension and a low venous oxygen tension. Thus a large arteriovenous difference in tension might result from increased oxygen consumption but is here caused by retarded circulation of the blood, perfusing oxygen at a slow rate.¹⁵ A low oxygen saturation of the venous

blood, which is a function of low oxygen tension, signifies here a low oxygen tension in the tissues. Campbell¹⁶ found that oxygen tension in the tissues closely approximates that of the venous blood. Therefore a venous congestion, as produced for therapeutic purposes, produces a relative anoxia in the tissues, followed by the repayment of the oxygen debt, a reactive hyperemia.

THE THERAPEUTIC APPLICATION OF ARTERIAL CONSTRICTION

Every surgeon has been impressed by the reactive hyperemia that follows the release of a tourniquet. The reactive hyperemia following arterial occlusion has been used by Cushing,¹⁷ who intended to paralyze the vasomotor nerves in applying arterial constriction during the attack of Raynaud's disease. The constriction was kept on for from one to two minutes. The patient completely recovered from her spasms even during the winter months. More recently the orthopedic literature contains favorable reports on alternate arterial constriction and release¹⁸ for exudates in joints and secondary vascular spasms. They combine this reactive hyperemia with an elevation of the leg to empty the blood after release. In this country Jordan¹⁹ reported very favorably on this form of treatment. He elevates the leg for one minute with a pulley, applies cuff pressure above systolic pressure for one minute, lowers the leg in the horizontal position and releases the cuff for another minute. The whole course lasts from fifteen to thirty minutes, or ten cycles of treatment.
